I would like to thank my advisor, Tom Heaton, for his great guidance on this project over the past 4 years. He was always enthusiastic and supportive of his students like a real father. Whenever I asked simple questions, he answered really sincerely and taught me something from his enormous knowledge of seismology.

The members of my advisory and defense committees, Jim Beck from Civil Engineering, Hiroo Kanamori and Rob Clayton from Seismolab, and Yih-Min Wu from Taiwan National University, were all very generous with their time and ideas. I especially thank Dr. Beck for giving me a guidance of probability theory. His contribution was very important for incorporating the Bayesian approach. Many thanks for Kanamori sensei, who talked me in a friendly and frank way whenever I visited his office. He gave me a lot of helpful advice for the physics of earthquakes.

I also appreciate people who provided me with seismic data and their research results, Brad Aagaard at the USGS, Chen Ji at UC Santa Barbara, Hiroo Kanamori, Jing Liu-Zeng at Institute of Tibetan Plateau Research, David Wald at the USGS, and Yih-Min Wu.

My thanks go to my fellow graduate students, Sai Hung Cheung, Anna Olsen, and Alexandros Taflanidis for helping me with research, exams, course work, and making the life in Thomas very enjoyable. Georgia Cua, who developed the Virtual Seismologist method, provides a lot of advice and support. I learned many things from her high-quality Ph.D. thesis. Support from Carolina Oseguera and all the members in Civil Engineering and Seismolab were also indispensable. Special thanks for all members in Caltech Japanese Association, I enjoyed life Caltech with them.

Above all, I am very thankful to my family in Japan. They are very patient and

always support my decisions. It was a big adventure for me to go to US and get a Ph.D. degree. My dream is accomplished thanks to their understanding.

# Abstract

Earthquake early warning systems have become popular these days, and many seismologists and engineers are making research efforts for their practical application. The existing earthquake early warning systems provide estimates of the location and size of earthquakes, and then ground motions at a site are estimated as a function of the epicentral distance and site soil properties. However, for large earthquakes, the energy is radiated from a large area surrounding the entire fault plane, and the epicenter indicates only where rupture starts.

In this project, we focus on an earthquake early warning system considering fault finiteness. We provide a new methodology to estimate rupture geometry and slip size on a finite fault in real time for the purpose of earthquake early warning.

We propose a new model to simulate high-frequency motions from earthquakes with large fault dimension: the envelope of high-frequency ground motion from a large earthquake can be expressed as a root-mean-squared combination of envelope functions from smaller earthquakes. We parameterize the fault geometry with an epicenter, a fault strike, and two along-strike rupture lengths, and find these parameters by minimizing the residual sum of squares of errors between ground motion models and observed ground motion envelopes.

To provide the information on the spatial extent of rupture geometry, we present a methodology to estimate a fault dimension of an earthquake in real time by classifying seismic records into near-source or far-source records. We analyze peak ground motions and use Bayesian model class selection to find a function that best classifies near-source and far-source records based on these parameters. This discriminant function is useful to estimate the fault rupture dimension in real time, especially for

large earthquakes.

In order to characterize slip on the fault in real time, we construct an analytical function to estimate slip on the fault from near-source ground displacement observations. In real-time analysis, we back project the recorded displacement data onto the fault line to estimate the size of the slip on the fault. The simulation results show that the slip size estimation predicts the observed GPS static displacement on the fault quite well. This current slip size on the fault is used for a probabilistic prediction of additional rupture length in the near future. We characterize the distribution of additional rupture length conditioned on the current slip on the fault for the ongoing rupture from the simulation with a 1-D slip model. The probability density of additional rupture length can be approximated by a lognormal distribution conditioned on the current slip size.

# Chapter 1

## Introduction

### 1.1 Motivation

Recently, with advances in data analysis and increased awareness of the seismic hazard, the topic of earthquake early warning has attracted more research attention, and various early warning methods have been proposed from seismologists and engineers (Nakamura and Tucker, 1988; Allen and Kanamori, 2003; Odaka et al., 2003; Wu and Kanamori, 2005a). Currently, the most ambitious system is the earthquake early warning system provided by the Japan Meteorological Agency, which is in a testing phase. The news of the system was broadcasted widely and attracted considerable public attention in Japan. The goal of seismic early warning is to initiate optimal mitigating actions based on the arrival time and amplitude of seismic waves predicted at a given location. To achieve this, an earthquake early warning system must collect and quickly analyze seismic data in a manner that can be used to predict future shaking. In principle, this could be achieved by using the present value of an approximately known wavefield as a boundary condition to predict future wavefields using Navier's equation (Baker et al., 2005). However, from a practical viewpoint, there are advantages to data analysis schemes that involve characterization of the earthquake source. Predictions of future shaking can be achieved by utilizing the extensive existing work on predicting ground shaking from seismic sources. Ideally, an early warning system would provide the best estimate of slip in time and space that can be deduced from seismic data available at any given instant in time.

Cua and Heaton developed the Virtual Seismologist (VS) method (Cua, 2005; Cua and Heaton, 2006). It is a Bayesian approach to seismic early warning designed for modern seismic networks, and is proposed for small to moderate earthquakes with ruptures that can be approximately modeled as a point source. The VS algorithm uses an envelope attenuation relationship and the predominant frequency content from the first few seconds after the P-wave arrival. The advantage of the VS method is its capacity to assimilate different types of information that may be useful to find quick and reliable estimates of magnitude and location (Cua, 2005). It gives the best estimate of an earthquake property in terms of a probability density function. The Bayesian approach is a scheme to emulate human capabilities to judge complex information by modeling uncertainty in a probabilistic way.

Our goal is to extend the VS method to large earthquakes where fault finiteness is important. Most other earthquake early warning systems focus on estimating epicenters and magnitudes of earthquakes, not the fault geometry (Nakamura and Tucker, 1988; Allen and Kanamori, 2003). However, for large earthquakes, rupture length can be on the order of tens to hundreds of kilometers, and the inhomogeneous slip distribution significantly affects the ground motion amplitude at a site. For example, the fault rupture in the 1999 Chi-Chi earthquake was longer than 80 km, and the largest slip was recorded at the northern end of the fault. It would be difficult, if not impossible, to predict such large shaking at large distances from the epicenter when using a scheme that only characterizes the earthquake as a point source.

Early warning for large earthquakes provides two types of predictions: 1) At a given instant, it recognizes the present geometry of an ongoing earthquake, and predicts the shaking from waves that are traveling to another site; 2) Given the present dimensions of a rupture, what is the probability distribution for the final dimensions of the rupture?

We introduce a two-step strategy to accomplish the first type of predictions; 1) we determine the spatial and temporal extent of an ongoing rupture by analyzing waveform envelopes of high-frequency shaking, 2) we determine approximate slip from simple projections of long-period shaking onto the approximately known location of

the rupture. Based on the current configuration of the fault, the second type of prediction can be accomplished.

## **1.2 Background on seismic early warning system**

### **1.2.1 History of research efforts in seismic early warning system**

Lee and Espinosa-Aranda (2003) and Kanamori (2005) provide a recent review and history of research efforts in seismic early warning. According to the quotation in Nakamura (1988), the concept of a seismic early warning system dates as far back as 140 years ago. Cooper (1868) proposed to “arrange a very simple mechanical contrivance at various points from 10 to 100 miles from San Francisco,” and “instantaneously ring an alarm bell, which should be hung in a high tower near the center of the city” when the “very simple mechanical contrivance” detects an earthquake. This article explains the fundamentals of a seismic early warning system. It refers to the automation of the system, danger of false alarms, and weakness of the system for very near-source earthquakes (see Appendix A for the quotation). Unfortunately, Cooper’s concept was never implemented. A hundred years later, a railway company, Japan Railways (JR) designed an earthquake warning system in 1965 and started operation the next year (Nakamura and Tucker, 1988; Nakamura, 1988).

In the United States, Heaton (1985) developed a model for a seismic computerized alert network (SCAN), which is a system to provide short-term warning for imminent strong ground motion from large earthquake in southern California. By using this model, the relationship between the size of the ground motions, warning time, and area where the warning is issued was analyzed. According to the results, although warning times are likely to be short for areas greatly damaged by relatively small to moderate earthquakes, large areas that experience very strong shaking during large earthquakes would receive longer warning times. He also comments that large earthquakes have a long rupture length, so the system can provide substantial warning

times. Toksöz et al. (1990) described a prototype earthquake warning system for strike-slip earthquakes whose slip can be approximated by only horizontal displacement. As the first practical application in US, a prototype early warning system for aftershocks was operated by the United States Geological Survey (USGS) in the San Francisco Bay area after the 1989 Loma Prieta earthquake,  $M_w=6.9$  (Bakun et al., 1994).

The concept of amplitude-based location estimate was introduced by Kanamori (1993). In his method, an attenuation relationship is fit to the observed peak acceleration data, and parameters of magnitude, latitude, and longitude are determined by minimizing the error between observations and predictions. This technique is the fundamental principle used in VS method. Kanamori et al. (1997) describe examples of seismic early warning system developed in several parts of the world. They discussed the current configuration of the seismic network in California and technical issues for providing real-time information. In the paper, they pointed out an issue that the energy is radiated from a large area for major earthquakes, and estimating the epicenter location is not enough to determine the ground motion at a site. It is proposed to locate not only the traditional hypocenter, but the center of the energy radiation, which is referred to as the ground motion centroid.

Kanamori (2005) classifies early warning approaches as either on-site or regional. An on-site approach uses available ground motions at a given site to predict the later-arriving main shock at the same site. This method is suitable for the region close to the epicenter. The regional approach predicts the ground motion at a site based on an estimate of the size and magnitude of the event from the near-source records. This approach is more reliable and provides more accurate information for stations relatively distant from the epicenter. The on-site approach can make a more rapid warning for the region close to the epicenter, since there is no need to compute the magnitude or location of the earthquake. On the other hand, the regional approach is useful for issuing a regional warning for the relatively distant stations. The merits and demerits of these approaches are shown in table 1.1.

Allen and Kanamori (2003) introduced the Earthquake Alarm System (ElarmS),

Table 1.1: On-site and regional approaches for the earthquake early warning system. Examples of each approach are explained in Section 1.2.2.

Type	On-site EWS	Regional EWS
Data to be used	Records of a station whose ground motion is estimated.	All the current available records.
Output information	Peak ground motion at a site. (additionaly, magnitude and epicenter location)	Source information. (ground motion at a site can be estimated from attenuation relationships)
Merits	Simple and quick.	Reliable and acculate.
Demerits	Large uncertainty.	Taking time for data collection and computation.
Suitable for	Regions close to the epicenter.	Relatively distant regions.
Examples	-UrEDAS (Nakamura, 1988) -ElarmS (Allen and Kanamori, 2003) -Taiwan EWS (Wu and Kanamori, 2005b)	-Mexico city SAS (Espinosa-Aranda et al., 1995) -Japan EWS (Odaka et al., 2003) -VS method (Cua, 2005)

which is an on-site approach for the California Integrated Seismic Network (CISN). This algorithm determines the magnitude of events from the predominant period of the first few seconds of the P-wave, based on the assumption that the seismic magnitude has a linear relationship with the predominant period of the ground motion. Wu and Kanamori (2005a) introduced an approach based on a predominant period and displacement amplitude for the Taiwan early warning system. The regional approach for seismic early warning is employed in Japan and Mexico (Odaka et al., 2003; Espinosa-Aranda et al., 1995, respectively). The VS method is also categorized as a regional approach.

## 1.2.2 Seismic early warning systems in the world

We review earthquake early warning systems that are currently in operation around the world (Normile, 2004).

### **1.2.2.1 Earthquake early warning system in Japan**

#### **1) Urgent Earthquake Detection and Alarm System (UrEDAS)**

The Bullet Train, or Shinkansen, of the Japan Railways (JR) started operation in 1964. The next year, Shizuoka earthquake (M6.1) hit the route of the train and damaged the train track. From the concern for the potential of serious damage from large earthquakes, the earthquake early warning system began operation in 1966 (Nakamura and Tucker, 1988). The system consists of accelerometers installed at the transforming stations along the train route, each separated by about 20 km (Nakamura and Tucker, 1988; Saita and Nakamura, 2003). When acceleration exceeds 40 gals, the electric power to the Bullet Train is automatically shut off and the brakes are applied (Nakamura and Tucker, 1988; Saita and Nakamura, 2003).

Starting from 1983, an intelligent earthquake warning system called UrEDAS (Urgent Earthquake Detection and Alarm System) was implemented (Nakamura, 1996b,a). In this upgraded system, the accelerometers are installed on the coastal line, which is closer to the Japanese subduction zone, to provide more warning time (Nakamura and Tucker, 1988). When the accelerometers record a strong ground motion, each station estimates the epicentral azimuth, magnitude, and hypocentral distance of the earthquake from the first few seconds of the records (Nakamura, 1996a). Based on this information, it then issues an alarm and automatically shuts off the electric power for trains which are running at high speed. The system worked during the Niigata Chuetsu earthquake in 2004. It immediately detected the P-wave arrival and shut off the train's power in less than 3 seconds (Nakamura et al., 2006).

#### **2) Early Warning System in Japan (extended Nowcast system)**

The Japan Meteorological Agency (JMA) and National Research Institute for Earth Science and Disaster Prevention (NIED) recently implemented a prototype emergency earthquake warning system in Japan (Doi, 2003; Odaka et al., 2003; Horiuchi et al., 2005).

It uses a method of estimating the epicentral distance from a single seismic record

in a short amount of time (Odaka et al., 2003). They fit a function  $Bt \cdot \exp(-At)$  to the initial part of the waveform envelopes of the past earthquakes and determine  $A$  and  $B$  by the least-squares method. It is found that the  $\log B$  is inversely proportional to  $\log$  of epicentral distance. Therefore, in real-time analysis, the observed envelopes are fit to the empirical function to estimate the epicentral distance.

After deciding distance estimate, they estimate the magnitude from the maximum amplitude observed within a given short time interval after the P-wave arrival by using an empirical magnitude-amplitude relation that includes the epicentral distance as a parameter. Using epicentral location, depth, and magnitude as input data, the amplitude of the maximum velocity on local site bedrock and the arrival time are estimated from a velocity attenuation relationship (Si and Midorikawa, 1999). In order to obtain the peak ground velocity estimate from the site bedrock velocity estimate, the latter is multiplied by a site amplification factor from an available database called the digital national land information. Currently, this early warning system is under going a testing phase, and the distribution of the early warning information is limited to the people in charge of emergency services.

#### **1.2.2.2 Seismic Alert System (SAS) of Mexico city**

Seismic Alert System (SAS) is a seismic early warning system for Mexico city (Espinosa-Aranda et al., 1995, 1996; Lee and Espinosa-Aranda, 2003). From the lesson of the aftermath of the 1985 Michoacan earthquake, the SAS was implemented to detect subduction earthquakes occurring in the Mexican subduction zone located several hundred kilometers south-west of Mexico city. The system consists of a seismic detector on the Pacific coast, telecommunications, central control, and radio warning. The local magnitude is estimated from an empirical relation embedded in each seismic detector, and a warning message is sent via the telecommunications unit if the estimated magnitude is greater than 6. The system is effective since Mexico city is located 300 km from the coast line and it takes about 1 minute for seismic waves to travel from the coast to the central city. The characteristics of the seismic damage in the Mexico city is the collapse of high-rise buildings because of the very soft soil

structure. The SAS would be more useful if the warning information is effectively used for those high-rise buildings.

### 1.2.2.3 Early warning system in Taiwan

Taiwan has established several research programs that are actively pursuing earthquake early warning and rapid reporting systems (e.g., Teng et al., 1997; Wu et al., 1998). The early warning system established by the Taiwan Central Weather Bureau (CWB) uses a real-time strong-motion accelerograph network consisting of 86 stations distributed around Taiwan (Wu and Kanamori, 2005b). The system takes an on-site approach and the predominant period ( $\tau_c$ ) and peak amplitude of displacement in the first 3 seconds after the P-wave arrival ( $Pd$ ) determine the seismic magnitude (Wu et al., 2006). Wu and Kanamori (2005a) also found that  $Pd$  correlates well with the peak ground displacement (PGD) and peak ground velocity (PGV) at the same site. Therefore, P-wave arrival time,  $\tau_c$ , and  $Pd$  can jointly be used to determine the hypocenter, magnitude, and the ground motion intensity at the site. For an event with the same location as the 1999 Chi-Chi earthquake, the Taipei metropolitan area, at 145 km from the epicenter, would have more than 20 sec of early warning time with this early warning system (Wu and Kanamori, 2005b).

### 1.2.2.4 Early warning system in the United States

The U. S. Geological Survey (USGS) has sponsored the development of a telemetered earthquake monitoring system in California to provide rapid earthquake information for the benefit of public safety, emergency response, and loss mitigation.

In Southern California, the CUBE (Caltech-USGS Broadcast of Earthquakes) project, started in 1991, had a goal to develop near real-time earthquake information systems (Kanamori and Hauksson, 1991). The seismic network in the original CUBE system used digital data from a seismic network with analog telemetry, which severely limited the dynamic range of the data. The increasing demand of rapid earthquake information after the 1994 Northridge earthquake led to the deployment of 24-bit digital communications as a part of the TriNet project (Heaton et al., 1996).

In northern California the REDI (Rapid Earthquake Data Integration) system was operated by the University of California at Berkeley in collaboration with the USGS. Since 1994, the CUBE and REDI systems have been upgraded to the California Integrated Seismic Network (CISN). Recently, Allen and Kanamori (2003) demonstrated the feasibility of a short-term earthquake warning using the extensive data set from CISN. The proposed system, ElarmS (Earthquake Alarm Systems), could issue a warning a few to tens of seconds ahead of damaging ground motion (Lockman and Allen, 2005; Simons et al., 2006; Allen, 2006). Currently, universities, federal and state government agencies, and the private sector are collaborating for the practical implementation of an early warning system on CISN.

#### **1.2.2.5 Early warning systems in other countries**

As a result of increased public perception of the benefits of earthquake early warning systems, such systems are being developed all over the world. Southern Europe is an earthquake-prone zone and their national and local governments have a great interest in mitigating seismic damage by installing seismic early warning systems.

In Campania Region, southern Italy, a prototype system for seismic early warning and rapid shake map evaluation is being developed and tested (Zollo et al., 2006).

In Istanbul, Turkey, one hundred strong motion accelerometers have been placed in populated areas, and ten strong motion stations are sited at locations as close as possible to the main fault (Great Marmara Fault) in on-line data transmission mode to provide earthquake early warning information (Zschau et al., 2003; Erdik et al., 2003).

Seismicity in Bucharest, Romania, has special properties such as the invariability of the location of epicenters and the stability of radiation patterns (Wenzel et al., 2003). A Mexico city-type SAS system would be adequate for those kinds of areas.

The city of Yerevan, Armenia, is planning to install 13-15 seismic detectors around the city with a radius of 30 km. Approximately 3 to 8 seconds of warning time is expected (Balassanian et al., 2003).

### 1.3 Objectives and road map for this thesis

In order to construct an early warning system for large earthquakes, we characterize the rupture extent and the slip on the fault in real time and predict ground motions at a given site based on the current rupture configuration. The objectives of this thesis are:

- Characterize the present rupture extent from high-frequency ground motions
- Characterize the present slip on the fault from low-frequency ground motions
- Predict the rupture extent from the on-going rupture.

The thesis is organized as follows: In chapter 1 we outline the research area of earthquake early warning systems and look at the previous research in this area. In chapter 2 we briefly discuss the basic procedures of the Virtual Seismologist (VS) method, a seismic early warning system developed by Cua and Heaton (Cua, 2005; Cua and Heaton, 2006). In chapter 3 we discuss a strategy to extend the VS method to large earthquakes. To work this problem, we first recognize the statistical observations of high-frequency and low-frequency ground motions for large earthquakes with magnitude greater than 6.0. In chapters 4 and 5 we introduce two different methodologies that can estimate the rupture geometry from acceleration envelopes. In the first method the rupture geometry can be characterized with three parameters, an azimuthal direction, and two rupture lengths, one in the positive direction and one in the negative direction, as measured from the epicenter. These parameters can be estimated from acceleration envelopes in real time. In chapter 5 we propose a technique to classify near-source and far-source stations. In chapter 6 we propose a methodology to determine the slip on the fault and predict the total length of the rupture propagation possible conditioned on the current slip. Finally, in chapter 7 we provide conclusions and future work.

## Chapter 2

# General Virtual Seismologist Method

In this chapter, we briefly discuss the basic procedures of the Virtual Seismologist (VS) method developed by Cua and Heaton (Cua, 2005; Cua and Heaton, 2006), which forms a foundation for the work in this thesis. The VS method is a Bayesian approach for seismic early warning systems. The Bayesian framework provides a means to incorporate previous experience and judgment that is not traditionally and explicitly incorporated into automated decision making. When making a decision, a human processes many kinds of information, combines and analyzes them simultaneously, and makes a judgment based on the analyzed information. The Bayesian approach is a scheme to emulate human capabilities to judge multiple pieces of information comprehensively and make judgements from limited information.

One component of the VS method is a method to estimate: 1) magnitude from observed ground motion ratios between vertical acceleration and vertical filtered displacement; and 2) magnitude and location from P- and S-wave amplitudes of vertical and horizontal acceleration, velocity, and filtered displacement. Any seismic early warning system estimates the earthquake information from the sparse set of available observations immediately after the initial P wave detection. What differentiates the VS method from other proposed seismic early warning systems is the use of prior information. Prior information (i.e. the state of health of the seismic network, fault locations, and previously observed seismic activity) can help to reduce the uncertainty

of the initial estimate of the event information.

## 2.1 Bayes' theorem for seismic early warning system

Bayes' Theorem is a simple mathematical formula to calculate conditional probabilities. The probability of event A conditioned on the occurrence of event B is called a posterior probability for the event A. This can be expressed as a normalized product of a prior probability density function (pdf) and a likelihood function:

$$\underset{\text{posterior}}{prob(A|B)} = \frac{\overset{\text{likelihood}}{prob(B|A)} \times \overset{\text{prior}}{prob(A)}}{\underset{\text{normalizing constant}}{prob(B)}} \quad (2.1)$$

The posterior probability for the earthquake early warning system is the probability of the parameter we would like to estimate (e.g., magnitude, location of the epicenter) given observed ground motion data (e.g., accelerograms, GPS displacement). For the VS method, Bayes' Theorem can therefore be expressed as:

$$\underset{\text{posterior}}{prob(M, R|A)} = \frac{prob(A|M, R) \times prob(M, R)}{prob(A)} \propto \underset{\text{likelihood}}{prob(A|M, R)} \times \underset{\text{prior}}{prob(M, R)}, \quad (2.2)$$

where  $A$  is the observed ground motion amplitude,  $M$  is the magnitude of the earthquake, and  $R$  is the location (i.e., latitude and longitude) of the epicenter. The posterior pdf,  $prob(M, R|A)$ , is proportional to the product of the prior pdf,  $prob(M, R)$ , and the likelihood function,  $prob(A|M, R)$ , since the constant,  $prob(A)$ , is independent of the magnitude and the location of the earthquake. The posterior pdf represents the conditional probability of magnitude and location when we observe the ground motion amplitude. The best estimation of the magnitude and location can be obtained by maximizing the posterior to give the most probable values (see Figure 2.1).

The likelihood function is the probability of the ground motion amplitude ob-

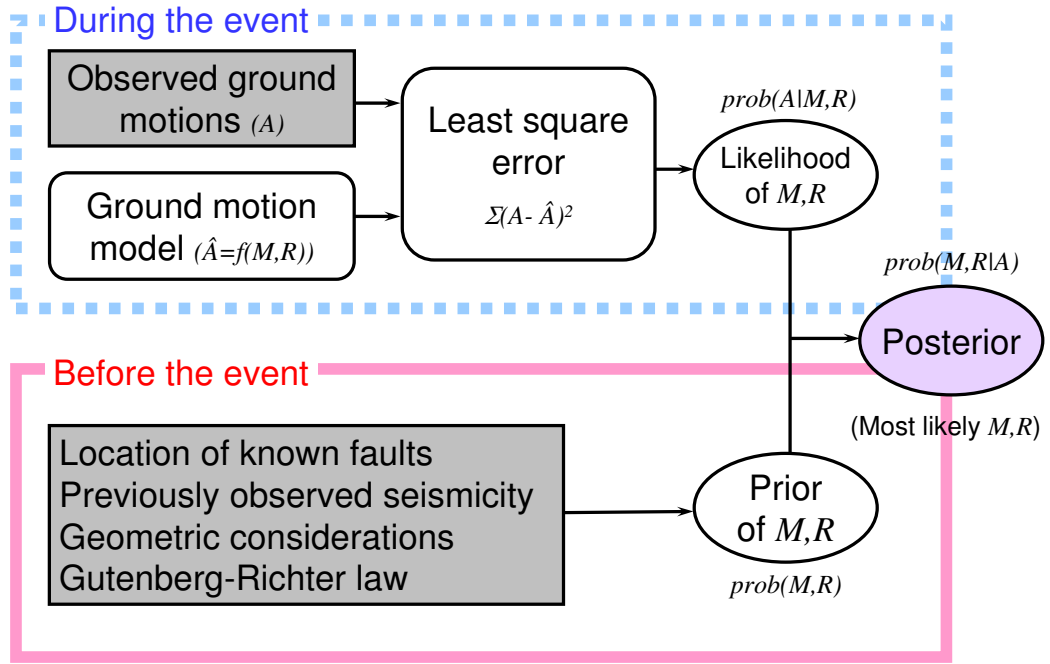

Figure 2.1: A block diagram to compute the posterior pdf of Bayes' theorem from the prior information and real-time ground motion data.

servation given the magnitude and distance. It is defined using a ground motion attenuation relationship for ground motion amplitudes in terms of magnitude and distance. The sum of square errors ( $\Sigma(A - \hat{A})^2$ ) is often used to define the likelihood function which corresponds to taking a Gaussian probability model for each prediction error, the error between the observation ( $A$ ) and prediction ( $\hat{A}$ ) based on the models. The Bayesian approach reduces to some other geophysical inverse methods if the prior information is not considered; then it is the same as the maximum likelihood method and corresponds to a least-square approach in the case of Gaussian prediction errors.

The prior pdf expresses information known before examining waveform data for the ongoing earthquake rupture. Station geometry, location of faults, or previously observed seismicity can be expressed as probability density functions and used as prior information. For example, the regions where earthquakes were observed on previous days have a higher probability of producing additional earthquakes. Therefore, the prior pdf is higher for regions that are near events on previous days. The prior pdf

is also higher for areas near known faults. Other prior information (e.g., station geometry, Gutenberg-Richter law) can be included in the same way.

## 2.2 Defining the prior $prob(M, R)$

The prior pdf is a probability of magnitude ( $M$ ) and location ( $R$ ) based only on the information obtained before an earthquake occurs. If there is no prior information, the magnitude and location of an earthquake are treated as equally likely to be any size and at any place, and so a uniform prior is used. However, generally speaking, there is usually some information before the initiation of an earthquake rupture, and that information can be used to constrain the magnitude and location estimates in seismic early warning. The following information is considered as prior information:

- Location of known faults
- Previously observed seismicity
- Geometric consideration of stations
- Gutenberg-Richter law

### 2.2.1 Location of known faults

Recognized active faults are more likely sources of future large earthquake than regions without recognized faults. Even though there are many faults hidden underground which are too small to extend from earthquake depths to ground level, the information of active faults helps to confine the source location. The prior pdf, considering the location of known faults, can be defined as an exponential function of the distance from fault lines (Felzer and Brodsky, 2006):

$$prob(r) = cr^{-1.34}, \quad (2.3)$$

where

$r$  = the shortest distance between fault lines and a station,  
 $c$  = constant.

An example of the prior pdf for the known faults is shown in Figure 2.2.

Figure 2.2: An example of the prior pdf for the known faults for the 2004 Parkfield earthquake. Solid lines indicate the location of the fault lines in California and darkness of the shade around the lines show higher prior pdf values. The star symbol shows the epicenter of the Parkfield earthquake.

### 2.2.2 Previously observed seismicity

Since observations of foreshocks preceding large earthquakes are significantly related to subsequent earthquakes, the regions where an earthquake was observed on the previous day have a higher probability of an earthquake occurrence (Abercrombie and Mori, 1996). Abercrombie and Mori (1996) found that 44% of the earthquakes in their California dataset had foreshocks. Therefore, the prior pdf is higher at regions near the source of events on the previous day. The prior pdf considering the previously

observed seismicity is expressed by the exponential function (Felzer and Brodsky, 2006):

$$prob(r) = cr^{-1.34}, \quad (2.4)$$

where

$$r = |\mathbf{x} - \mathbf{x}_i|,$$

$\mathbf{x}$  = location of the station,

$\mathbf{x}_i$  = location of the foreshock epicenter ( $i = 1, \dots, n$ ),

$c$  = constant.

An example of the prior pdf for the known faults is shown in Figure 2.3.

Figure 2.3: An example of the prior pdf for the previously observed seismicity of the 2004 Parkfield earthquake. Open circles indicate the location of the previously observed seismicity and darkness of the shade around the circle show higher prior pdf values. The star symbol shows the epicenter of the Parkfield earthquake.

### 2.2.3 Geometric consideration of stations

Station geometry also provides a geometric constraint to the location of an earthquake epicenter. Rydelek and Pujol (2004), Cua (2005), and Horiuchi et al. (2005) developed a new technique to constrain the location of an earthquake from the P-wave arrival time using the Voronoi cell concept (Sambridge, 1999a,b). The Voronoi cell of a station is a convex polygon around the station, which is a set of all points closer to a station than to any other stations. The location of the earthquake epicenter must be inside of the Voronoi cell of the station first triggered by a P-wave arrival (Figure 2.4).

Figure 2.4: Voronoi cells of strong motion stations for 2004 Parkfield earthquake. Triangles denote strong motion station locations. The shaded region is that of possible location of epicenter when the closest station PKD detects the first P-wave arrival. The star symbol shows the epicenter of the Parkfield earthquake.

After the first P-wave arrives at the first station, not-yet-arrived data can shrink the probable region of the epicenter location inside the Voronoi cell (Figure 2.5). From Rydelek and Pujol (2004), the region of likely location of the epicenter based on the first two P-wave arrivals forms a hyperbola, which is a set of points the difference of whose distances from the first and the second arrival stations is a given positive

Figure 2.5: Voronoi cells of strong motion stations for 2004 Parkfield earthquake. Triangles denote strong motion station locations. The shaded region is that of possible location of epicenter at the 3 seconds after the first P-wave detection. The star symbol shows the epicenter of the Parkfield earthquake.

constant  $k$  (Figure 2.6). Furthermore, the use of not-arrived data after the first two P-wave arrivals can provide continuously evolving constraints on the region of likely location.

Figure 2.6: Voronoi cells of strong motion stations for 2004 Parkfield earthquake. Triangles denote strong motion station locations. The shaded region is that of possible location of epicenter at the second P-wave detection. The star symbol shows the epicenter of the Parkfield earthquake.

### 2.2.4 Gutenberg-Richter law

The Gutenberg-Richter law states that the number of earthquakes per year,  $N$ , of Richter magnitude  $M$  is statistically proportional to  $10^{-bM}$  (see Figure 2.7). This relationship is mathematically expressed as:

$$N(M) = 10^{a-bM}, \quad (2.5)$$

where  $a$  and  $b$  are constant, and the size of the constant  $b$  is typically around 1.

According to the Gutenberg-Richter law, there are a lot more small earthquakes than large ones. Therefore, the prior pdf corresponding to the Gutenberg-Richter law is defined as:

$$\text{prob}(M) \propto 10^{a-bM}. \quad (2.6)$$

Figure 2.7: Histogram of the magnitude of the earthquakes in Southern California during 2000~2006. The distribution follows the Gutenberg-Richter law.

## 2.3 Defining the likelihood function $prob(A|M, R)$

The likelihood function is the probability of the ground motion amplitude observation ( $A$ ) given the magnitude ( $M$ ) and distance ( $R$ ). Cua (2005) defined a likelihood function in terms of the ratio between vertical acceleration and displacement amplitudes, and the envelope attenuation relationships for vertical acceleration and horizontal acceleration, velocity, and displacement. This section describes the magnitude ground motion relationships, P-wave and S-wave discriminant, and ground motion models as components of the likelihood function.

### 2.3.1 Magnitude ground motion relationships

Magnitude ground motion relationship is one of the measurements to find magnitude of an earthquake from the ground motion. Many seismologists have pointed out that the P-wave predominant period is linearly correlated with the ultimate magnitude (Nakamura and Tucker, 1988; Allen and Kanamori, 2003). Cua and Heaton (2006) use ratios of the ground motion as indicative of the predominant frequency of the seismograms. Since the acceleration is equal to the square of frequency ( $\omega^2$ ) times displacement in the frequency domain, the magnitude is proportional to the ratio between acceleration and displacement.

$$\begin{aligned} M &\propto \omega_0^{-1} \\ &= c_1 \log(\text{acceleration}) + c_2 \log(\text{displacement}) + c_3, \end{aligned} \tag{2.7}$$

where  $\omega_0$  is the predominant frequency of the ground motion, and  $c_1, c_2$ , and  $c_3$  are coefficients. Cua (2005) performed a linear discriminant analysis with over 30,000 seismograms in Southern California to determine these coefficients. Figure 2.8 shows the dataset and the most probable linear discriminant function which classifies the dataset with different magnitudes. The best magnitude ground motion relationship is:

Figure 2.8: Linear discriminant analysis of P-wave  $\log(\text{acc})$  and  $\log(\text{disp})$  as indicators of magnitude.  $Z = X_2 \cdot u = 0.36 \log(\text{acc}) - 0.93 \log(\text{disp})$  (Cua, 2005).

$$\hat{M} = \begin{cases} -1.627(0.36 \log(Z_{\text{acc}}) - 0.93 \log(Z_{\text{disp}})) + 8.94 & : \text{ if P-wave,} \\ -1.459(0.36 \log(Z_{\text{acc}}) - 0.93 \log(Z_{\text{disp}})) + 8.05 & : \text{ if S-wave,} \end{cases} \quad (2.8)$$

where  $Z_{acc}$  and  $Z_{disp}$  are vertical acceleration and vertical displacement, respectively and standard deviations are:

$$\sigma = \begin{cases} 0.45 & : \text{ if P-wave,} \\ 0.41 & : \text{ if S-wave.} \end{cases} \quad (2.9)$$

By using this relationship, the observed and predicted ground motion ratios in equation 2.19 are expressed as follows:

$$Z_i = 0.36 \log(Z_{acc}) - 0.93 \log(Z_{disp}), \quad (2.10)$$

$$\hat{Z}_i(M) = \begin{cases} (-M + 8.94)/1.627 & : \text{ if P-wave,} \\ (-M + 8.05)/1.459 & : \text{ if S-wave.} \end{cases} \quad (2.11)$$

### 2.3.2 P-wave and S-wave discriminant

In equation 2.11, the magnitude ground motion relationship is defined separately for P-wave and S-wave. Although it is not significantly sensitive to whether the observed amplitudes are P- or S-wave (see equation 2.11), we can obtain better source estimates if we can identify phases (Cua, 2005). Cua (2005) defined a discriminant function as a linear combination of ground motion measures, and found the best combinations and coefficients for seismograms in Southern California by linear discriminant analysis. The result of the P/S wave discriminant is shown in figure 2.9. The most probable discriminant function is:

$$\begin{aligned} PS &= 0.44 \log(Z_{acc}) + 0.55 \log(Z_{vel}) - 0.46 \log(H_{acc}) - 0.55 \log(H_{vel}) \quad (2.12) \\ &= \log\left(\frac{Z_{acc}^{0.44}}{H_{acc}^{0.46}}\right) + \log\left(\frac{Z_{vel}^{0.55}}{H_{vel}^{0.55}}\right), \end{aligned}$$

Figure 2.9: P/S wave discriminant using vertical and horizontal ground motion acceleration and velocity (Cua, 2005).

$$if \begin{cases} PS > 0 : \text{P-wave,} \\ PS < 0 : \text{S-wave,} \end{cases}$$

where  $Z_{acc}$ ,  $Z_{vel}$ ,  $H_{acc}$ , and  $H_{vel}$  are vertical acceleration and velocity, and horizontal acceleration and velocity, respectively.

### 2.3.3 Ground motion models

Cua and Heaton examined over 30,000 seismograms in Southern California and developed relationships that predict waveform envelopes as a function of magnitude,

distance and station corrections (Cua, 2005; Cua and Heaton, 2006). First, the envelopes of the ground motions are modeled as a combination of the envelopes of P-wave, S-wave, and ambient noise.

$$E_{observed}(t) = \sqrt{E_P^2(t) + E_S^2(t) + E_{ambient}^2} + \epsilon, \quad (2.13)$$

where

$E_{observed}(t)$  = envelope of observed ground motion,

$E_P(t)$  = envelope of P-wave,

$E_S(t)$  = envelope of S-wave and later-arriving phases,

$E_{ambient}$  = ambient noise at the site,

$\epsilon$  = difference between predicted and observed envelope.

The ambient noise,  $E_{ambient}$ , for a given time history is modeled as a station constant. The P- and S-wave envelopes,  $E_P(t)$  and  $E_S(t)$ , are defined by a rise time ( $t_{rise_P}$  and  $t_{rise_S}$ ), a constant amplitude ( $A_P$  and  $A_S$ ), a duration ( $\Delta t_P$  and  $\Delta t_S$ ), and two decay parameters ( $\gamma_P$  and  $\gamma_S$ ) and ( $\tau_P$  and  $\tau_S$ ) respectively. See figure 2.10 for the physical interpretation of these parameters.

The general form of the envelope function is:

$$E_{ij}(t) = \begin{cases} 0 & ; \quad t < T_i, \\ \frac{A_{ij}}{t_{rise_{ij}}}(t - T_i) & ; \quad T_i \leq t < T_i + t_{rise_{ij}}, \\ A_{ij} & ; \quad T_i + t_{rise_{ij}} \leq t < T_i + t_{rise_{ij}} + \Delta t_{ij}, \\ A_{ij} \frac{1}{(t - T_i - t_{rise_{ij}} - \Delta t_{ij} + \tau_{ij})^{\gamma_{ij}}} & ; \quad t \geq T_i + t_{rise_{ij}} + \Delta t_{ij}, \end{cases} \quad (2.14)$$

Figure 2.10: Observed envelope for accelerogram and P-wave and S-wave envelopes for the ground motion model defined in equation 2.14 (Cua, 2005).

where

$i = \text{P-, S-wave,}$

$T_i = \text{P-, S-wave arrival times,}$

$j = \text{horizontal and vertical acceleration, velocity, and displacement.}$

Cua and Heaton parameterized each seismogram as a set of eleven parameters (five for the P-wave envelope, five for the S-wave envelope, and one for the ambient noise). Furthermore, each parameter is described by magnitude, distance, log of distance, and site dependent constants based on the traditional strong motion attenuation relationships (Campbell, 1981; Boore and Joyner, 1982; Boore et al., 1993). The functional forms which describe the P- and S- wave envelope functions are given below:

$$\log_{10} A_{ij} = a_{ij}M + b_{ij}(R_1 + C_{ij}(M)) + d_{ij} \log_{10}(R_1 + C_{ij}(M)) + e_{ij} + \epsilon_{ij}, \quad (2.15)$$

$$\log_{10} B_{ij} = a_{ij}M + b_{ij}R_1 + d_{ij} \log_{10} R_1 + e_{ij} + \epsilon_{ij}, \quad (2.16)$$

where

$i$  =P-, S-wave,

$j$  =horizontal and vertical acceleration, velocity, and displacement,

$A_{ij}$  =ground motion envelope amplitude,

$B_{ij}$  =rise time ( $t_{rise}$ ), duration ( $\Delta T$ ), and decay parameters ( $\tau, \gamma$ ),

$M$  =local magnitude ( $M_w$  for  $M > 5.0$ ),

$R$  = epicentral distance in km for  $M < 5$ ,

closest distance to fault for  $M > 5.0$  (when available),

$$R_1 = \sqrt{(R^2 + 9)},$$

$$C_{ij}(M) = (\arctan(M - 5) + 1.4)(c_{1ij} \exp(c_{2ij}(M - 5))),$$

$a_{ij}, b_{ij}, c_{1ij}, c_{2ij}, d_{ij}, e_{ij}$  =regression constants,

$\epsilon_{ij}$  =statistical (or prediction) error,  $\sim NID(0, \sigma^2)$ .

The  $A_{ij}$ s are the ground motion envelope amplitudes (P- or S-wave) from fitting equations 2.13 and 2.14 to the observed ground motion envelopes in the database. The  $B_{ij}$ s are the parameters characterizing the envelope function ( $t_{rise}$ ,  $\Delta T$ ,  $\tau$ , and  $\gamma$ ). Coefficients in equations 2.15 and 2.16 are determined by regression analysis of the database using the Neighborhood Algorithm (described later in Section 4.2). An example of set of coefficients (for horizontal and vertical accelerations on soil sites) are shown in table 2.1. Table 2.1 and equations 2.13 – 2.16 can determine the envelope function of ground motions with magnitude  $M$  and epicentral distance  $R$ . Figure 2.10 shows an observed ground motion envelope and the best P-wave, S-wave, and ambient noise envelopes based on equations 2.13 – 2.16.

Table 2.1: Coefficients for the envelope attenuation relationships for rms horizontal and vertical acceleration on a soil site in equation 2.16. All attenuation relationships model  $\log_{10}$  of the envelope parameter as functions of magnitude and distance (Cua, 2005).

### 2.3.4 Complete form of the likelihood function

As we discussed at the top of this section, the likelihood function is defined in terms of the ground motion ratio between vertical acceleration and displacement amplitudes, and the envelope attenuation relationships for vertical acceleration and horizontal acceleration, velocity, and displacement.

The ground motion ratio estimates the magnitude of earthquakes. To find the

best estimate, the error between the observation and prediction from the magnitude ground motion relationships is minimized.

$$prob(Z_i|M) = \frac{1}{\sqrt{2\pi}\sigma_{Z_i}} \exp\left(-\frac{(Z_i - \hat{Z}_i(M))^2}{2\sigma_{Z_i}^2}\right), \quad (2.17)$$

where

$i=1, \dots, n$ , where  $n$  is the number of stations with  $P$  detections,

$\sigma_{Z_i}$  = standard deviation in equation 2.9,

$Z_i$  = observed ground motion ratio in equation 2.10,

$\hat{Z}_i$  = ground motion ratio predicted by the magnitude ground motion, relationship in equation 2.11.

The amplitude of the ground motion envelopes estimate the magnitude and location of earthquakes. The errors between the observed envelopes and predicted envelopes from the ground motion models are also approximated by a Gaussian distribution.

$$prob(Y_{ijk}|M, R) = \frac{1}{\sqrt{2\pi}\sigma_{ijk}} \exp\left(-\frac{(Y_{ijk} - \hat{Y}_{ijk}(M, R))^2}{2\sigma_{ijk}^2}\right), \quad (2.18)$$

where

$j=1, \dots, 4$ , for peak amplitudes of vertical velocity, and

horizontal acceleration, velocity, and displacement,

$k=1, \dots, nt$ , time in 1-second intervals from the event onset,

$\sigma_{ijk}$  = standard deviation of  $j$  channels and time  $k$  at station  $i$

$Y_{ijk} = \log_{10}$  of peak observed amplitude of  $j$  channels and time  $k$  at station  $i$

$\hat{Y}_{ijk} = \log_{10}$  of peak amplitude of  $k$  channels and phase  $j$  at station  $i$

predicted by ground motion models in equations 2.13 – 2.16

The vertical acceleration and displacement are used to estimate the magnitude, and the amplitudes of the vertical velocity and three horizontal components solve the trade-off between the magnitude and location of the epicenter. From equations 2.17 and 2.18, the likelihood function of 1-second-interval ground motion envelopes ( $A$ ) conditioned on the magnitude ( $M$ ) and location ( $R$ ) is:

$$\begin{aligned} prob(A|M, R) &= \prod_{i=1}^n \prod_{j=1}^4 \prod_{k=1}^{nt} prob(Z_i|M) prob(Y_{ijk}|M, R) \\ &\propto \exp \left[ - \sum_{i=1}^n \left( \frac{(Z_i - \hat{Z}_i(M))^2}{2\sigma_{Z_i}^2} + \sum_{j=1}^4 \sum_{k=1}^{nt} \frac{(Y_{ijk} - \hat{Y}_{ijk}(M, R))^2}{2\sigma_{ijk}^2} \right) \right]. \end{aligned} \quad (2.19)$$

## 2.4 Finding the best estimates

In order to operate the VS method in real time, we first assume that seismic waveform data are transmitted to a central processor by a seismic network with sufficient station density to quickly characterize the seismic wave field. The central processing station processes currently available seismic records and produces updates as additional data are received. The prior probability incorporated in the real-time Bayesian analysis includes information about magnitude likelihood (e.g., Gutenberg-Richter frequency magnitude) and location likelihood (e.g., known faults, or previously observed seismicity). This prior pdf has been calculated before the occurrence of any earthquake which the VS method is intended to provide a warning for. As the seismic data arrives, the processor can use it to evaluate the likelihood function for any location and size of the earthquake in order to maximize the posterior in equation 2.2 to get the best estimate of magnitude and location of the earthquake; this is done using updated information every second. The predicted ground motion at any site can be computed by the ground motion model in equations 2.13 and 2.14, since a magnitude and distance define the ground motion envelope uniquely in the model. This strategy assumes a point-source model and works for small to moderate earthquakes (magnitude  $< 6.5$ ).

## 2.5 Summary

In this chapter, we briefly discussed the basic procedures of the VS method developed by Cua and Heaton (Cua, 2005; Cua and Heaton, 2006).

The VS method is a Bayesian approach for seismic early warning systems. It incorporates prior information which can be obtained before an event and a likelihood function computed from the ground motion data available after the initial P-wave detection, and finds the most probable estimate for magnitude and location by maximizing the posterior, which is equivalent to maximizing the product of prior pdf and likelihood function.

We discussed how to define prior pdf and likelihood function from available set of data in this chapter. The location of known faults, and previously observed seismicity, geometric consideration of stations, and Gutenberg-Richter law are considered as the prior information. Likelihood function is defined in terms of the magnitude ground motion relationship and envelope ground motion amplitudes. More detail about the VS method and examples of the application of the VS method are shown in Cua's Ph.D. thesis (Cua, 2005).

## Chapter 3

# Extended Virtual Seismologist Method

This chapter discusses a strategy to extend the Virtual Seismologist method to large earthquakes. We obtain the finite-rupture information by inverting high-frequency and low-frequency ground motions respectively. To understand this procedure, it is important to recognize the characteristics of high-frequency and low-frequency ground motions. This chapter also analyzes the statistical features of observed high-frequency and low-frequency ground motions for large earthquakes with magnitude greater than 6.0.

### 3.1 Road map for Virtual Seismologist Finite-Source method

The previous chapter briefly discusses the general VS method. In its current level of development, this methodology seems effective for earthquakes ( $M < 6.5$ ), where rupture can be modelled with a point source. However, for large earthquakes, rupture length can be on the order of tens to hundreds of kilometers, and the heterogeneous slip distribution significantly affects the ground motion amplitude expected at a site. For example, the fault rupture in the 1999 Chi-Chi earthquake was longer than 80 km, and the largest slip was recorded near the end of the rupture at the northern end of the fault. It would be difficult, if not impossible, to predict such large shaking at

large distances from the epicenter when using a scheme that only characterizes the earthquake as a point source.

In order to extend the VS method to earthquakes with  $M > 6.5$ , we need to consider the fault rupture geometry and the size of slip on the fault. To differentiate the VS method considering the fault finiteness, we call the general VS method described in the previous chapter “VS Point-Source (PS) method” and the VS method for large earthquakes “VS Finite-Source (FS) method.”

Our strategy for large earthquakes is as follows. (See also figure 3.1.)

01

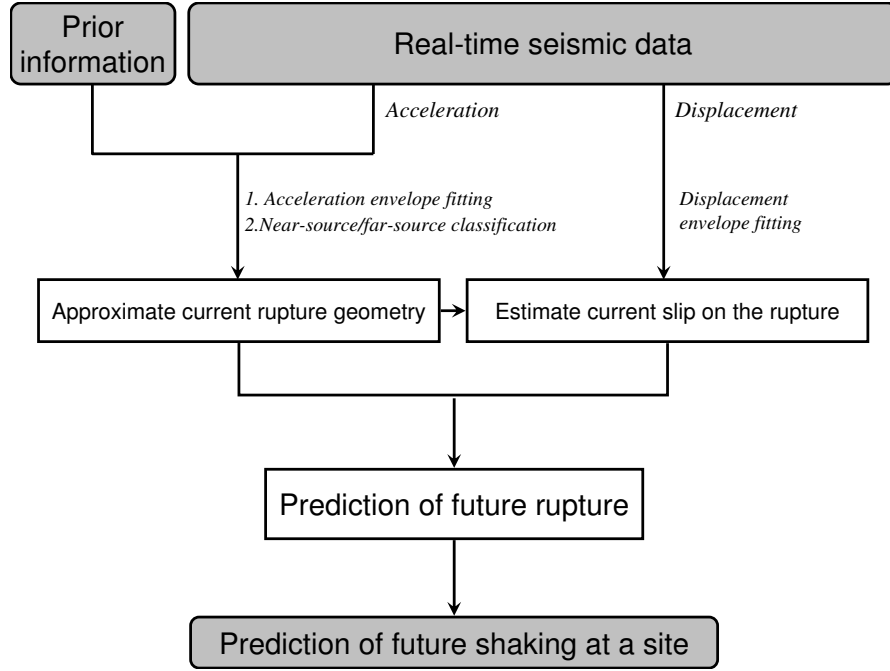

Figure 3.1: The algorithm of the VS method for finite source (VS-FS method). First, we estimate the rupture geometry from the accelerations by the methods discussed by Yamada and Heaton (2006) and Yamada et al. (2006). Based on this geometry, slip on the fault can be estimated from displacement records. By combining current rupture information and prior information, the predicted probability of rupture extent can be obtained.

### 1) Apply the VS-PS method

First, apply the VS-PS method to the ongoing rupture. Estimate the epicenter and magnitude of an event when the closest stations record the P-waves. If the magnitude is less than a certain threshold (e.g.  $M < 5.5$ ), the estimated location and magnitude of the earthquake is accepted. If it exceeds the threshold, then there is a reasonable possibility that the earthquake is large, and it might not be adequately modeled as a point source. In this case, we apply VS Finite-Source (FS) method to find the location of the finite fault.

### 2) Estimating the current rupture extent

The VS-FS method determines the ongoing rupture geometry in real time from high frequency ground motions. Acceleration records are used to estimate the temporal and spatial evolution of the rupture front. Use of Bayes' theorem in equation 2.1 is also helpful here. The posterior pdf of the problem of estimating a rupture extent is the probability of the rupture location ( $S$ ) given observed ground motion data ( $A$ ). Bayes' Theorem for the problem to estimate rupture geometry is:

$$prob(S|A) \propto prob(A|S) \times prob(S). \quad (3.1)$$

The prior  $prob(S)$  is information known before examining waveform data, such as the location of known faults. Large earthquakes often occur on recognized active faults, and information about the location and activity of these faults is potentially a valuable set of prior information. After an earthquake initiates and ground motion data becomes available, the likelihood function will be computed.

The likelihood function  $prob(A|S)$  is the probability of the ground motion amplitude observation given the rupture location. Two separate methodologies have been developed to estimate the evolving rupture geometry:

i) the multiple source model described in chapter 4 determines the rupture geometry that best predicts the envelopes of high-frequency ground motions (Yamada and Heaton, 2006); and

ii) a near-source versus far-source station discriminator in chapter 5 has been developed which allows us to map the location of an ongoing rupture front (Yamada et al., 2006).

These techniques are used to characterize the likelihood function. They are also valuable for predicting the future ground motions.

### 3) Estimating size of the current slip on the fault

We determine the slip on the fault that is compatible with both the observed low-frequency motions and also with the rupture geometry determined from high-frequency motions. Aagaard et al. (2004) simulated near-source ground motions and investigated the near-source displacement as a function of distance from the fault. We use the result of their simulations to characterize the slip on the fault, and construct an analytical function to estimate slip on the fault from observations of displacement away from the fault.

The probability of the slip on the fault ( $D$ ) given the rupture geometry and real-time seismic data is also written by Bayes' Theorem:

$$prob(D|A, S) \propto prob(A|D, S) \times prob(A|S). \quad (3.2)$$

The likelihood function  $prob(A|D, S)$  is the probability of the ground motion amplitude observation given rupture location and size of the slip. Substituting  $prob(A|S)$  from equation 3.1, the probability is expressed as:

$$prob(D|A, S) \propto prob(A|D, S) \times prob(A|S) \times prob(S). \quad (3.3)$$

Currently, the displacement data is obtained from the double integration of strong motion accelerations, and it can be difficult to remove erroneous baselines in real-time analysis. However, quite a few high-frequency GPS—which record displacement directly—are installed these days, so we assume displacement data will be available in real time. In real-time analysis, we back project the recorded displacement data

onto the fault line to estimate the size of the slip on the fault. The fault slip makes it possible to predict long-period seismic waves, which is important to estimate seismic damage. The current size of the slip on the fault allows for a probabilistic prediction of additional rupture in the near future.

#### 4) Predicting the probability of rupture extent

We also create a methodology to predict the total length of the rupture propagation conditioned on the current slip size. Liu-Zeng et al. (2005) created a methodology to generate simple 1-D models of spatially heterogeneous slip. By using this methodology, we compute the probability of the final rupture length ( $L$ ) conditioned on the current slip on the fault ( $D$ ) in a statistical way. Intuitively, a rupture is much more likely to terminate in the near future if its present value is small. Our final goal is to predict final rupture extent from ground motion data available in real time.

### 3.2 Statistics of observed high-frequency and low-frequency ground motions

The ground motions at a site could be different for different earthquakes of the same magnitude at the same distance, because of differences in source mechanisms, path effect, or site conditions. One of the most commonly used ground motion parameters is peak ground acceleration (PGA), and Campbell (1981) found that the uncertainty of peak ground acceleration can be modeled using a lognormal distribution. In other words, the distribution of the amplitude of ground motions with constant magnitude and distance follows a lognormal distribution.

Studies of near-source records show that the high frequency ground motion saturates as a function of magnitude for large earthquakes, and it weakly depends on the magnitude in the near-source (Hanks and Johnson, 1976; Joyner and Boore, 1981; Hanks and McGuire, 1981). Therefore, if we constrain the size of the magnitude greater than a certain number, the distribution of the near-source PGA of those

earthquakes can be assumed to be a lognormal distribution.

However, the low frequency ground motion has a strong correlation with the magnitude of an earthquake, as we see in the formula of the seismic moment and average slip on the fault. We use power law distributions to describe the statistics of near-source peak ground displacement (PGD). Gutenberg-Richter Law of earthquake magnitudes obeys a power law. The number of earthquakes per year of magnitude  $M$  is proportional to the base-ten exponential of the magnitude  $M$ . The relationship between magnitude and the PGD is expected to be a power law distribution, i.e., the PGD increases as seismic magnitude becomes large.

In this section, we analyze near-source PGA and PGD of 10 major earthquakes with magnitude greater than 6.0 and show the near-source ground motion distributions.

### 3.2.1 Data

We investigate strong motion datasets of ten earthquakes with magnitude greater than 6.0 and containing records of near-source stations. The earthquakes are shallow crustal earthquake with focal depths less than 25 km. The selected earthquake dataset is shown in table 3.1. Here, we defined the near-source station as a station with fault distance less than 10 km. Fault models used to determine the fault distance are also shown in table 3.1. 147 near-source records are used in total.

Those near-source accelerograms are processed according to the following method. The DC offset of accelerograms is corrected by subtracting the mean of the pre-event portion. This process sets the initial velocity and displacement to zero, which is important because a small DC offset has a large effect when the record is integrated. This process is used for all accelerograms.

The horizontal peak ground motions are calculated by the square root of the sum of the squares of the peak value of the EW and NS components. The vertical peak ground motions are the peak value of the UD component. The following processes are completed for all the data.

Table 3.1: Earthquake data set used for the near-source ground motion analysis. Moment magnitude ( $M_w$ ) and focal depth are cited from Harvard CMT solution. The preliminary determination of epicenter is used for the focal depth. The definition of the near-source station is a station with fault distance less than 10 km. The numbers of near-source data for each earthquake are also shown. The fault models are used as selection criteria to classify near-source stations.

Earthquake	$M_w$	Records	Focal Depth	Fault Model
Imperial Valley (1979)	6.5	14	12.0	Hartzell and Heaton (1983)
Loma Prieta (1989)	6.9	8	19.0	Wald et al. (1991)
Landers (1992)	7.3	1	15.0	Wald and Heaton (1994)
Northridge (1994)	6.6	17	16.8	Wald et al. (1996)
Hyogoken-Nanbu (1995)	6.9	4	20.3	Wald (1996)
Izmit (1999)	7.6	4	17.0	Sekiguchi and Iwata (2002)
Chi-Chi (1999)	7.6	42	21.2	Ji et al. (2003)
Denali (2002)	7.8	1	15.0	Tsuboi et al. (2003)
Parkfield (2004)	6.0	47	12.0	Ji et al. (2004)
Niigataken-Chuetsu (2004)	6.6	9	13.0	Honda et al. (2005)
Total		147		

**Acceleration:** The accelerograms from which the DC offset is corrected are used to compute the PGA.

**Displacement:** The accelerograms from which the DC offset is corrected are integrated twice in the time domain and high-pass filtered using a forth-order Butterworth filter with a corner frequency of 0.075 Hz, avoiding most complications due to baseline shifts. However, the computed PGD from filtered displacement records can be significantly smaller than actual PGD.

Since it is difficult to compute the actual peak displacement, the filtering process is performed. The computed PGD from filtered displacement records are much smaller than actual PGD.

### 3.2.2 Statistics of observed high-frequency ground motions

Based on the collected near-source ground motion data (i.e., horizontal and vertical components of the PGA and PGD), we examine the statistical features of the near-source ground motions for large earthquakes.

Figure 3.2: A plot of near-source (fault distance less than 10 km) PGA as a function of moment magnitude. The dashed lines are trendlines for the horizontal and vertical component and the regression equations are shown on the plot.

Figure 3.3: A histogram of the near-source (fault distance less than 10 km) PGA for earthquakes with magnitude  $\geq 6.0$ . The dashed lines are lognormal distribution fitting to the histograms. The circles on the x-axis indicate the geometric mean of each component. The values of the geometric means and natural log of the geometric standard deviations are shown on the plot ( $\mu$  and  $\sigma$ ).

Figure 3.2 shows horizontal and vertical near-source PGA in this dataset as a function of moment magnitude. Even though data from the same earthquake are scattered, the slope of regression line is almost equal to zero. Based on the two tailed Student's t-test, these slopes fall inside of the 95% confidence interval of the zero slope. This is consistent with past studies which indicate the high frequency ground motion at near-source region saturate as a function of magnitude for large earthquakes.

We also examine the marginal distribution of PGA. Figure 3.3 show histograms of horizontal and vertical PGA. The horizontal and vertical acceleration histograms show a good fit to the lognormal distribution. This is reasonable since the uncertainty of PGA for earthquakes of the same magnitude at the same distance can be modeled using a lognormal distribution. Also, the PGA of near-source stations weakly depends on the magnitude for large earthquakes. Therefore, all the PGA data with magnitude greater than 6.0 are approximately independent of magnitude and lognormally distributed.

### 3.2.3 Statistics of observed low-frequency ground motions

The distributions of horizontal and vertical PGD as a function of moment magnitude are shown in figure 3.4. The log of PGD is proportional to the magnitude. The high frequency motion does not depend on magnitude for large earthquake and observed PGA do not exceed 2g. However, low frequency motion is highly correlated with magnitude, and the amplitude seems to follow a power law. There is evidence that average fault slip ( $\bar{D}$ ) scales with rupture length ( $L$ ), even for large earthquake (Scholz, 1982; Liu-Zeng et al., 2005). In this case we expect that seismic moment  $M_0 \propto L\bar{D} \propto \bar{D}^2$  for large crustal earthquakes. Since moment magnitude  $M \propto 2/3 \log M_0$ , we expect that  $\log \bar{D} \propto 3/4 M$ . If near-source ground displacement is a linear function of the fault slip and rupture length ( $L$ )  $\gg$  rupture width ( $W$ ), then we expect that near source displacement should scale as  $3/4 M$ . The slopes of the near-source ground displacement in figure 3.4 are 0.6 and 0.71 for horizontal and vertical components,

respectively. These numbers are consistent with this theoretical interpretation.

Figure 3.4: A plot of near-source (fault distance less than 10 km) PGD as a function of moment magnitude. The dashed lines are trendlines for the horizontal and vertical component and the regression equations are shown on the plot.

The histogram of PGD does not follow a lognormal distribution. We discuss the theoretical form of the PGD distribution.

From the Gutenberg Richter Law,  $N_E$ , the number of earthquakes having magnitude greater than  $M$ , is proportional to the base-ten exponential of  $-M$ .

$$N_E \propto 10^{-M}, \quad (3.4)$$

$$\frac{dN_E}{dM} \propto 10^{-M}. \quad (3.5)$$

Since the moment scales as 2/3 of log of the product of average slip ( $\bar{D}$ ) and fault rupture area ( $S$ ), equation 3.5 becomes:

$$\begin{aligned} N_E &\propto 10^{-\log(\bar{D}S)^{2/3}} \\ &\propto (\bar{D}S)^{-2/3}. \end{aligned} \quad (3.6)$$

Figure 3.5: A histogram of the near-source (fault distance less than 10 km) PGD for earthquakes with magnitude  $\geq 6.0$ . The circles on the x-axis indicate the geometric mean of each component and their values are shown on the plot ( $\mu$ ).

We assume the number of the near-source stations is proportional to the fault rupture area ( $S$ ) times station distribution density ( $\rho_s$ ). The number of records ( $N_r$ ) of earthquakes with magnitude  $M$  is:

$$\begin{aligned}
 N_r &\propto N_E \times S \times \rho_s \\
 &\propto (\bar{D}S)^{-2/3} S \rho_s \\
 &\propto \bar{D}^{-2/3} S^{1/3} \rho_s.
 \end{aligned} \tag{3.7}$$

Assuming homogeneous station distribution ( $\rho_s = \text{constant}$ ), equation 3.7 is:

$$N_r \propto \bar{D}^{-2/3} S^{1/3}. \tag{3.8}$$

The fault rupture surface is equal to the product of fault rupture length ( $L$ ) and fault rupture width ( $W$ ). For large earthquakes,  $L \gg W$ , and  $W$  has an upper limit (Scholz, 1982). Assuming constant stress drop, the average slip scales as the fault

rupture area, which is proportional to the rupture length ( $\bar{D} \propto S \propto L$ ). Substituting this relationship into equation 3.8,

$$N_{ns} \propto \bar{D}^{-2/3} S^{1/3} \quad (3.9)$$

$$\propto \bar{D}^{-2/3} \bar{D}^{1/3} \quad (3.10)$$

$$\propto \bar{D}^{-1/3}. \quad (3.11)$$

This shows that the number of records of earthquakes with a certain amplitude slowly decays with its amplitude. Our observations of large earthquakes are too few to verify this theory experimentally, and there are some assumptions which do not hold in our dataset (e.g., homogeneous station distribution). However, this simple derivation considering the Gutenberg Richter Law and fault rupture dimension shows that the probability that a site will experience large ground displacement is not as small as we can ignore. In figure 3.5, the distribution of PGD does not seem to follow the distribution in equation 3.11, but it shows records of large ground displacements as many as those of small ground displacements. This observation is important for high-rise buildings, telling us there are high probability that buildings are subjected to large ground displacements.

### 3.2.4 Comparison of high-frequency and low-frequency ground motions

We compare horizontal PGA and PGD distributions in figures 3.6 and 3.7. Figure 3.6 shows the moment magnitude versus PGA and PGD. The amplitudes of the PGA and PGD are normalized by the geometric mean of each. The PGA saturate as a function of moment magnitude, and the slope of the trendline is about zero. On the other hand, the PGD trendline is log proportional to the moment magnitude.

Figure 3.7 shows the histogram of horizontal PGA and PGD normalized by the geometric mean of each component. The PGA follows a lognormal distribution centered at  $464 \text{ cm/s}^2$ . The variance for the high-frequency motions is smaller than that

Figure 3.6: A comparison of near-source PGA and PGD as a function of moment magnitude. The dashed lines are trendlines for each component. The numbers on the plot ( $\mu$ ) are the geometric mean of each component.

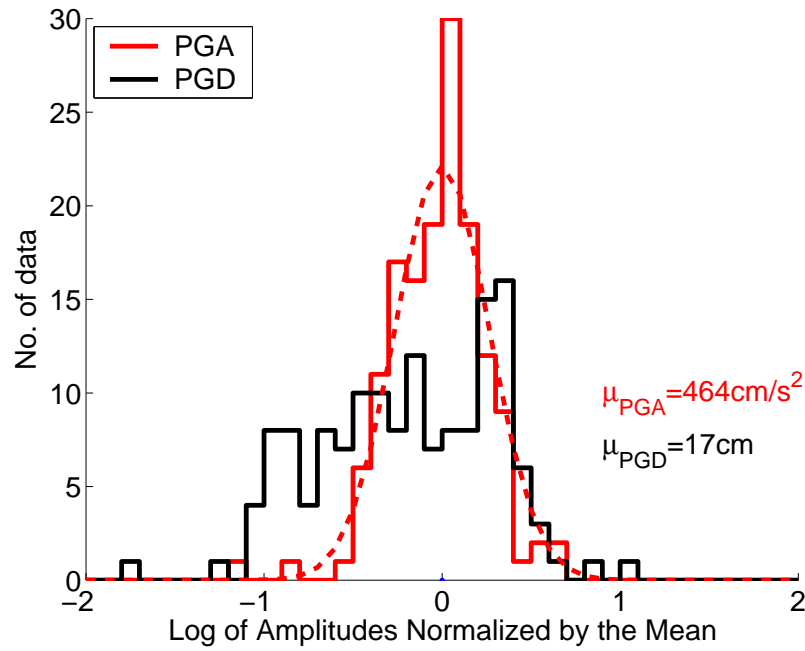

Figure 3.7: A histogram of the near-source PGA and PGD for earthquakes with magnitude  $\geq 6.0$ . The numbers on the plot ( $\mu$ ) are the geometric mean of each component.

of the low-frequency motions. This is reasonable since the high-frequency ground motions saturate as a function of magnitude, the variance of PGA is not as large as that of PGD.

### 3.2.5 Definitions of the horizontal component

The horizontal component in this thesis is computed by the square root of the sum of squares of peak EW component and peak NS component. However, there are other definitions for the horizontal acceleration.

For example, in some cases, a peak value over time of the largest of the two accelerations from each of the recorded horizontal channel is also used. We compared the three different definitions of horizontal components.

(1) square root of sum of squares (srss) horizontal components =  $\sqrt{\max(EW)^2 + \max(NS)^2}$  : the square root of sum of squares of peak EW component and peak NS component.

(2) magnitude of horizontal vector =  $\max(\sqrt{EW^2 + NS^2})$  : peak over time of the amplitude of the srss horizontal acceleration vector.

(3) root mean squares (rms) horizontal components =  $\sqrt{\frac{1}{2}(\max(EW)^2 + \max(NS)^2)}$  : the root mean squares of peak EW component and peak NS component.

It is obvious that the rms horizontal components in definition (3) is  $\sqrt{1/2}$  as large as the srss horizontal components in definition (1), so the horizontal components only in definition (1) and (2) are compared.

Figures 3.8 and 3.9 show the PGA and PGD as a function of magnitude, and figures 3.10 and 3.11 show the distributions of PGA and PGD. For both PGA and PGD, the definition (1) is a little larger than definition (2). The geometric means of PGA for definition (1) and (2) are 464 cm/s<sup>2</sup> and 393 cm/s<sup>2</sup>, and the geometric means of PGD for definition (1) and (2) are 17.0 cm and 15.3 cm. Therefore, the definition (2) is 85% smaller for PGA, and 90% smaller for PGD, than the definition (1). This means it is easy to estimate the horizontal component of one definition from

that of the other definition.

Figure 3.8: Comparison of the srss horizontal PGA (definition (1)) and magnitude of horizontal accelerations (definition (2)) as a function of magnitude. The regression curves and regression equations are also shown in the plot.

Figure 3.9: Comparison of the srss horizontal PGD (definition (1)) and magnitude of horizontal displacements (definition (2)) as a function of magnitude. The regression curves and regression equations are also shown in the plot.

Figure 3.10: A histogram of the srss horizontal PGA (definition (1)) and magnitude of horizontal accelerations (definition (2)) for earthquakes with magnitude  $\geq 6.0$ . The numbers on the plot ( $\mu$ ) are the geometric mean of each acceleration.

Figure 3.11: A histogram of the srss horizontal PGD (definition (1)) and magnitude of horizontal displacements (definition (2)) for earthquakes with magnitude  $\geq 6.0$ . The numbers on the plot ( $\mu$ ) are the geometric mean of each displacement.

### 3.3 Summary

In this chapter, we explained a strategy to extend the VS-PS method to large earthquakes. For large earthquakes, the rupture length can be on the order of tens to hundreds of kilometers, and the heterogeneous slip distribution significantly affects the ground motion amplitude at a site. In order to estimate the size and location of an earthquake or the expected ground motion at a given site, we need to characterize the fault geometry and size of the slip on the fault in real time.

The statistical features of high-frequency and low-frequency ground motions for large earthquakes with magnitude greater than 6.0 were analyzed. The observations show that the near-source peak ground accelerations saturate as a function of magnitude for large earthquakes, and is almost independent of magnitude if the magnitude is greater than 6.0. The marginal distribution of PGA follows the lognormal distribution with mean 464 and 211  $\text{cm/s}^2$  for the horizontal and vertical acceleration, respectively. On the other hand, the near-source low frequency ground motion for large earthquakes has strong correlation with the magnitude of an earthquake, and the PGD scales by a power law with the magnitude.

We compute the horizontal components of ground motion from three definitions and compare the results. The three definitions (srss horizontal components, magnitude of horizontal vector, and rms horizontal components) are linear scale of each other. The horizontal component of one definition can be estimated from that of the other definition.

For early warning of large earthquakes, we use high-frequency seismic radiation to determine ongoing fault rupture geometry in real-time and low-frequency ground motion to estimate the slip on the fault. In chapters 4 and 5, we propose two approaches to determine the ongoing fault rupture geometry from accelerograms in real time. In chapter 7, we focus on estimating slip on the fault in real time and the probabilistic prediction of additional rupture in the near future.

## Chapter 4

# Estimating the Location of Fault Rupture Using Envelopes of Acceleration

Early warning information based on a point-source model may underestimate the ground motion at a site, if a station is close to the fault and distant from the epicenter. This occurs because, for large earthquakes, the peak characteristics of ground motion, such as peak ground acceleration, have stronger correlation with the fault rupture distance rather than with the epicentral or hypocentral distance (Campbell, 1981). (The definition of the fault rupture distance in this paper is the shortest distance between the station and the surface projection of the fault rupture surface.)

In order to construct an early warning system that is more reliable for large earthquakes, it is necessary to estimate the fault rupture extent and slip on the fault in real time. The VS-FS method uses high-frequency ground motions to estimate the temporal and spatial evolution of the rupture. Two separate methodologies have been developed to estimate the evolving rupture geometry:

- i) the multiple source model described in this paper determines the rupture geometry that best predicts the envelopes of high-frequency ground motions (Yamada and Heaton, 2006) and

- ii) a near-source versus far-source station discriminator has been developed which allows us to map the location of an ongoing rupture front (Yamada et al., 2006).

In this chapter, we introduce a methodology that can estimate the rupture ge-

ometry from acceleration envelopes. The second methodology will be introduced in the next chapter. In this analysis, we characterize the rupture geometry with three parameters, an azimuthal direction, and two rupture lengths, one in the positive direction and one in the negative direction as measured from the epicenter. These parameters can be estimated from acceleration envelopes in real time.

## 4.1 Ground motion models for large earthquakes

As we saw in the previous chapter, accelerations recorded close to a rupture saturate at magnitudes larger than 6, whereas distant sites do not demonstrate comparable saturation as a function of magnitude. Examples of the near-source accelerations and their envelopes are shown in figures 4.1 - 4.4. The envelope functions (Cua, 2005) are made from the dataset including earthquakes with magnitudes ranging between 2 and 7, assuming point-source model. Therefore, we need a new envelope function which can fit the acceleration envelopes of large earthquakes.

We introduce a multiple source model to express the fault finiteness. The fault surface is divided into subfaults, and each subfault is represented by a single point source, called “subsources” (figure 4.5). To simplify the problem, we assume that the dimensions of all subsources are uniform. Each source nucleates, and the P- and S-waves are radiated when the rupture front arrives at the subsurface.

The ground motion at a site is modeled as the combination of the responses of each subsurface. For high-frequency motions with approximately random phase, we found that the square root of the sum of the squares of the envelope amplitudes from each subsurface provides a good estimation of an acceleration envelope.

$$E_{total}(t) = \sqrt{\sum_{i=1}^n E_i(t)^2}, \quad (4.1)$$

where  $E_{total}(t)$  is the estimated envelope as a function of time,  $E_i(t)$  is the envelope of the  $i$ th source, and  $n$  is the total number of subsources.  $E_i(t)$  is actually a fairly complex function of time, magnitude, distance, and station corrections, although its

Figure 4.1: Near-source accelerations in the vertical component.

Figure 4.2: Envelopes of near-source accelerations in the vertical component.

Figure 4.3: Near-source accelerations in the EW component.

Figure 4.4: Envelopes of near-source accelerations in the EW component.

Figure 4.5: Schematic diagram of the multiple source model. The fault rupture is assumed to propagate from the epicenter at the constant velocity  $v_R$ . The fault is parameterized by  $\theta$ ,  $N1$ , and  $N2$ , where  $\theta$  is the azimuthal angle of the fault,  $N1$  and  $N2$  are the number of sub-sources north and south of the epicenter, respectively. The ground motion at a station is expressed as a combination of the envelope from each sub-source.

forward calculation is very fast since it only involves analytic functions (Cua, 2005; Cua and Heaton, 2006).

This model only works for high-frequency ground motions. Unlike longer-period ground motions, high-frequency motions seem to be insensitive to either radiation pattern (Liu and Helmberger, 1985) or directivity (Boatwright and Boore, 1982). Furthermore, near-source high-frequency motions saturate as a function of magnitude. That is, near-source high-frequency ground motions are independent of the amplitude of the slip for large earthquakes (Kanamori and Jennings, 1978; Cua and Heaton, 2006).

Heaton and Hartzell (1989) pointed out that the assumptions of a Brune (1970)

source spectrum combined with constant stress drop leads to high-frequency energy radiated from a subfault that is independent of the slip on the subfault. A consequence of the fact that high-frequency near-source ground motions can be modeled as random noise whose amplitude is independent of slip is that the high-frequency radiated energy in earthquakes is proportional to the rupture surface area. This is consistent with the observation of Boatwright (1982), who showed that high-frequency spectral acceleration amplitudes are proportional to the root-mean-square (rms) dynamic stress drop and the square root of the rupture area. Our simple model for simulating high-frequency motions is also compatible with the observation of Hanks and McGuire (1981) that high-frequency ground accelerations are remarkably similar from one event to another. Subsources for our multiple source model are evenly spaced, so the surface area and high-frequency radiated energy corresponding to each subsource are also constant. Based on this theoretical interpretation, we estimated the ground motion envelopes with the multiple source model for the 1999 Chi-Chi earthquake.

Figure 4.6 (top) shows an example of predicted envelopes for vertical accelerations using the multiple source model. It shows the envelopes of the vertical acceleration record for each subsource with magnitude 6.0. Figure 4.6 (bottom) shows the time history envelope of the accelerogram (vertical component) at the station C024, a station on the foot wall side and 10 km from the Chelungpu faultline (shown in figure 4.7, southwest of the epicenter). Figure 4.6 also shows that the vertical acceleration envelopes predicted by the multiple source model for the VS-FS method fit the observed envelopes much better than the envelopes predicted by the single source model for the VS-PS method.

Even though the Ch-Chi rupture has large spatial variations in the amplitude of the slip, it appears that the high-frequency accelerations can be modeled as a sum of the radiation from a uniform tiling of the magnitude 6.0 subfaults, based on the random-phase assumption and saturation with regard to magnitude.

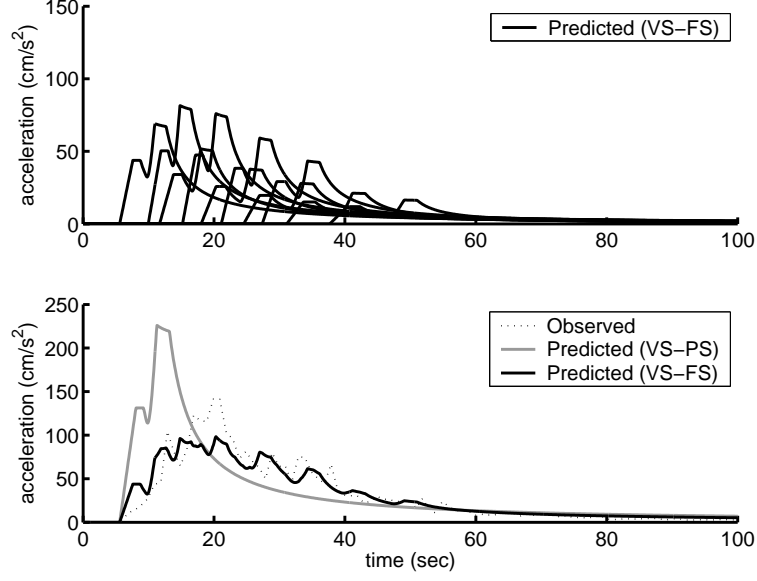

Figure 4.6: Envelopes of vertical acceleration recorded at the station C024 for the Chi-Chi earthquake. Top: predicted envelopes of the vertical acceleration record for each subsource with magnitude 6.0. Bottom: Observed envelope (in dotted black line), and predicted envelopes of the point-source model in VS-PS method (in solid gray line) and of the multiple source model in VS-FS method (in solid black line).

## 4.2 Finding the best estimates

We assume that the location of the epicenter is already estimated from the VS-PS method, and that the fault ruptures bilaterally from the epicenter with constant rupture velocity. Thus, the time delay for each subsource rupture is the distance from the epicenter divided by the rupture velocity. Therefore, parameters that we need to estimate from the observed data are the azimuthal angle ( $\theta$ ) of the rupture direction, and N1 and N2, that are used to simulate each of the segments of the bilateral rupture.

The best estimate of the model parameters minimizes the residual sum of the squares (RSS) between observed ground motion envelopes and predicted envelopes from the multiple source model. The misfit function as a measure of goodness of fit

is defined as follows:

$$RSS(t) = \sum_{i=1}^{ns} \sum_{j=1}^2 \sum_{k=1}^t (A_{ijk} - \hat{A}_{ijk})^2, \quad (4.2)$$

where  $ns$  is the number of stations,  $t$  is the time in 1 second intervals ( $\Delta t = 1$ ) from the event onset, and  $A_{ijk}$  and  $\hat{A}_{ijk}$  are observed and predicted envelopes of component  $j$  at station  $i$  at time  $k\Delta t$ .

This form of the misfit function tends to emphasize the importance of fitting stations with large accelerations. That is, distant stations have small observed and predicted accelerations and even if there are serious discrepancies in the ratio of the predicted and observed amplitudes, they will have little impact on the inversion. The results of different misfit functions are shown in Section 4.3.5.

Our parameterization scheme has the advantage that we characterize the source with relatively few parameters ( $\theta$ , N1, N2), none of which require high-precision estimates. However, for this strategy to be effective, we will need to solve a nonlinear inverse problem in real time. In this study, we solve this nonlinear inverse problem by using the Neighborhood Algorithm (Sambridge, 1999a,b). We recognize that other inverse techniques may ultimately be chosen for real-time applications. However, since the purpose of this study is to determine the effectiveness of our parameterization, we use the Neighborhood Algorithm to characterize and solve this nonlinear inverse problem.

The Neighborhood Algorithm is a direct search method for finding models of acceptable data fit in a multidimensional parameter space. We generate samples in the parameter space and draw the Voronoi cells for these samples. Voronoi cells are nearest neighbor regions defined under a suitable distance norm, and the shape and the size of each Voronoi cell is determined by the sample distribution in the parameter space. See figure 4.7 as an example of Voronoi cells that are used to define the nearest neighbors to seismic stations. We calculate the misfit function for each sample and choose the model with the lowest misfit. New samples are generated by performing a uniform random walk in the chosen Voronoi cell. By repeating these steps, we will

Figure 4.7: The fault geometry and the station distribution of the Chi-Chi earthquake. The shaded area around the epicenter displays the map projection of the fault geometry proposed by Ji *et al.* (2003). Small circles indicate the location of subsources determined based on the fault model. The area within 50 km and 100 km from the epicenter is shown by large circles. Stations used in this analysis are shown by solid triangles. The polygon surrounding each station is the Voronoi cell for the station.

find a set of samples that identifies those regions of the parameter space that provide the best fit to the data. This is an approach for constructing the posterior probability density function from the ensemble samples based on the Voronoi cell concept.

## 4.3 Example from the Chi-Chi earthquake

### 4.3.1 Data used for the VS-FS method

The data for this analysis is the strong motion dataset from the 21 September 1999 Chi-Chi Earthquake that occurred in central Taiwan (Lee et al., 2001). The epicenter

was located at 120.82 N, 23.85 E, with a focal depth of 8 km according to the Central Weather Bureau (CWB) of Taiwan (Shin and Teng, 2001). It is currently the largest well-recorded earthquake with moment magnitude 7.6. 441 strong motion stations recorded the main event, and 69 of those were at distances of less than 50 km from the epicenter. We use three component (NS, EW, and UD) strong motion records from the data set collected by CWB. They classified the recorded accelerograms into four quality groups based on the existence of absolute timing, pre-events, and defects. For this analysis, we use QA-class data (best for any studies), QB-class data (next best but no absolute timing) and a part of QC-class data (covering the principal strong motions but not having pre-event or post-event data) which includes the pre-event. Stations of which we use the records are shown in 4.8. The color code of each station indicates soil condition. Cua (2005) classified those station classes into a binary rock-soil classes. Class A and B are classified as “rock,” and class C, D, and E as “soil.” Most of the stations in Taiwan are class C and below, so we use the ground motion model for soil only. Figure 4.8 shows that the soil conditions of the stations corresponds to the geographical formation. Western part of the Taiwan island is soft soil basin, where most of the major cities are located. Eastern part of the island is mountainous area, and there are not many stations. On the east coast, there are cities such as Yilan or Hualien where station distribution is very high. The Chi-Chi earthquake occurred at the boundary of western basin and eastern mountains. Around the epicenter the station distribution is very inhomogeneous (see figure 4.11): there are many stations on the west side (foot-wall side of Chelungpu fault) and few stations on the east side (hanging-wall side of Chelungpu fault).

Figures 4.9 – 4.11 are closer looks of figure 4.8 with station code. The station code has four characters: the first alphabet is an abbreviation of the district, and the last three numbers are a sequencing number. Prefix “C” indicates Chiayi, “H,” Hualien, “I,” Yilan, “N,” Taitung, “P,” Taipei, and “T,” Taichung.

Table 4.1 describes the crustal model for P-wave and S-wave velocity in central Taiwan (Ma et al., 1996). P-wave and S-wave arrival time for the predicted envelope are computed with this 1-D layered crustal model. Since the original seismic records

Table 4.1: P-wave and S-wave velocity model in central Taiwan (Ma et al., 1996).

Thickness(km)	$V_p$ (km/s)	$V_s$ (km/s)
1.0	3.50	2.00
3.0	3.78	2.20
5.0	5.04	3.03
4.0	5.71	3.26
4.0	6.05	3.47
8.0	6.44	3.72
5.0	6.83	3.99
0.0	7.28	4.21

reported incorrect universal time, we use the data modified by Lee et al. (2001). They compared picked P-wave arrival times with computed theoretical P-wave arrival times. If the P-time residual was larger than 1 second for accelerograms at the distance within 50 km, they corrected the P-wave arrival time (Lee et al., 2001). Therefore, the error of the time stamp of the modified data is less than 1 second.

### 4.3.2 Results from the analysis of the VS-FS method

We have run many different inversions by varying both the inversion parameters and the data sampling, such as the number of records used for the inversion, the components of the records, etc. Table 4.2 contains a list of the models investigated. We consider model 1 as a standard against which all other models are compared. It uses the horizontal and vertical records of the stations within 120 km of the epicenter.

Table 4.2: Model parameters for estimating a fault geometry. Distance is the maximum epicentral distance of the records used for the inversion. Component H and V stand for the horizontal and vertical component respectively. See the text for the area weight and data sampling.

Model	No. of stations	Distance(km)	Component	Area weight	Data sampling
1	239	120	H + V	-	-
2	239	120	H	-	-
3	239	120	V	-	-
4	239	120	H + V	X	-
5	126	120	H + V	-	even only
6	56	120	H + V	-	6 and 8 only

To simplify the problem, we assume each subsource has the same magnitude 6.0 and is located at the same depth, 8 km. The distance between each virtual source is 10 km. We assume constant rupture velocity to construct the predicted envelopes from subsources. In order to check the sensitivity of the parameter estimate to the rupture velocity, we run four simulations for model 1 with different rupture velocities. Figure 4.12 shows the estimated parameters, N1 and N2, for the rupture velocities from 2.0 km/s to 3.5 km/s. Even though we let the rupture velocity be faster than the real rupture velocity 2.0 km/s (Ji et al., 2003), N1 and N2 do not increase faster than 2 km/s (one per 5 seconds). In other words, the way that N1 and N2 change with the duration of the data tells us the rupture velocity. For the following simulations, we use the constant rupture velocity 2.0 km/s.

Figure 4.12: The estimated parameters,  $N1$  and  $N2$ , for different rupture velocities. The solid thin lines are the upper limits for  $N1$  and  $N2$  for the rupture velocity 2 km/s and 3.5 km/s. The broken lines are the best estimates based on the fault model proposed by Ji et al. (2003). Time is relative to the origin. The parameters are computed at each second using only the data available at that time.

### 4.3.3 Comparison between predicted envelopes and observed envelopes

Figures 4.13 and 4.14 are a comparison of observed envelopes and predicted envelopes for model 1. Figures 4.15 and 4.16 are the same waveforms as figures 4.13 and 4.14 with different scaling (the waveforms are scaled so that the peak amplitude of the predicted envelopes becomes a unit length). The best-fit source model for model 1 consists of 14 subsources distributed along a line trending 17 degrees clockwise from north; there are 7 subsources north of the epicenter and 4 subsources to the south. That is, the best fitting model 1 is given by ( $\theta=17$  degrees,  $N1=7$ ,  $N2=4$ ). The predicted acceleration envelopes for this model agree well with the observed envelopes.

Predicted envelopes of near-source stations have some discrepancy depending on the source process, but predicted envelopes of far-source stations fit the observation well.

The vertical predicted envelopes of the stations in the epicentral region (e.g., stations T078, T079, T084, and T089; see 4.17 and 4.18) are of particular interest. Model 1 overestimates these observed envelopes for the first 10 seconds, but then underpredicts the observed records 20 seconds after the earthquakes origin. The fact that the largest accelerations in the epicentral region occurred 20 seconds after the origin time seems to indicate that there may have been some rupture complexity in the hypocentral region; perhaps there was an early aftershock in the epicentral region 20 seconds after the first rupture. Although this feature is noteworthy, it does not have a significant effect on the inversions since the epicentral stations are less important for estimating azimuthal angle and length of the fault.

Note that there is a discrepancy between the predicted and observed horizontal envelopes of the stations along the east coast of Taiwan, especially near Hualien around 40 seconds after the origin time (see figures 4.15 and 4.16). The observed envelopes of those stations have large amplitudes which cannot be captured by the predicted envelopes. The P-wave and S-wave should arrive at Hualien about 15 and 26 seconds after the origin time, respectively, based on the velocity structure in central Taiwan (table 4.1). That is, the large amplitude at Hualien is neither a first arrival P-wave or S-wave. While critically reflected shear waves off the Moho discontinuity have been suggested for large amplitude high-frequency phases at similar distances (Somerville and Yoshimura, 1990), the large amplitude waves on the east coast of Taiwan seem too late to be Moho critical reflections. Perhaps a secondary triggered event occurred east of the epicenter.

Another major discrepancy is the sharp pulse that appears about 40 seconds after the event onset in the records of stations located about 40 km north of the recognized northern terminus of the Chelungpu fault rupture (e.g., stations T045, T047, and T095). Shin and Teng (2001) suggested that these large accelerations were generated by a secondary rupture, perhaps on the Shihtan fault.

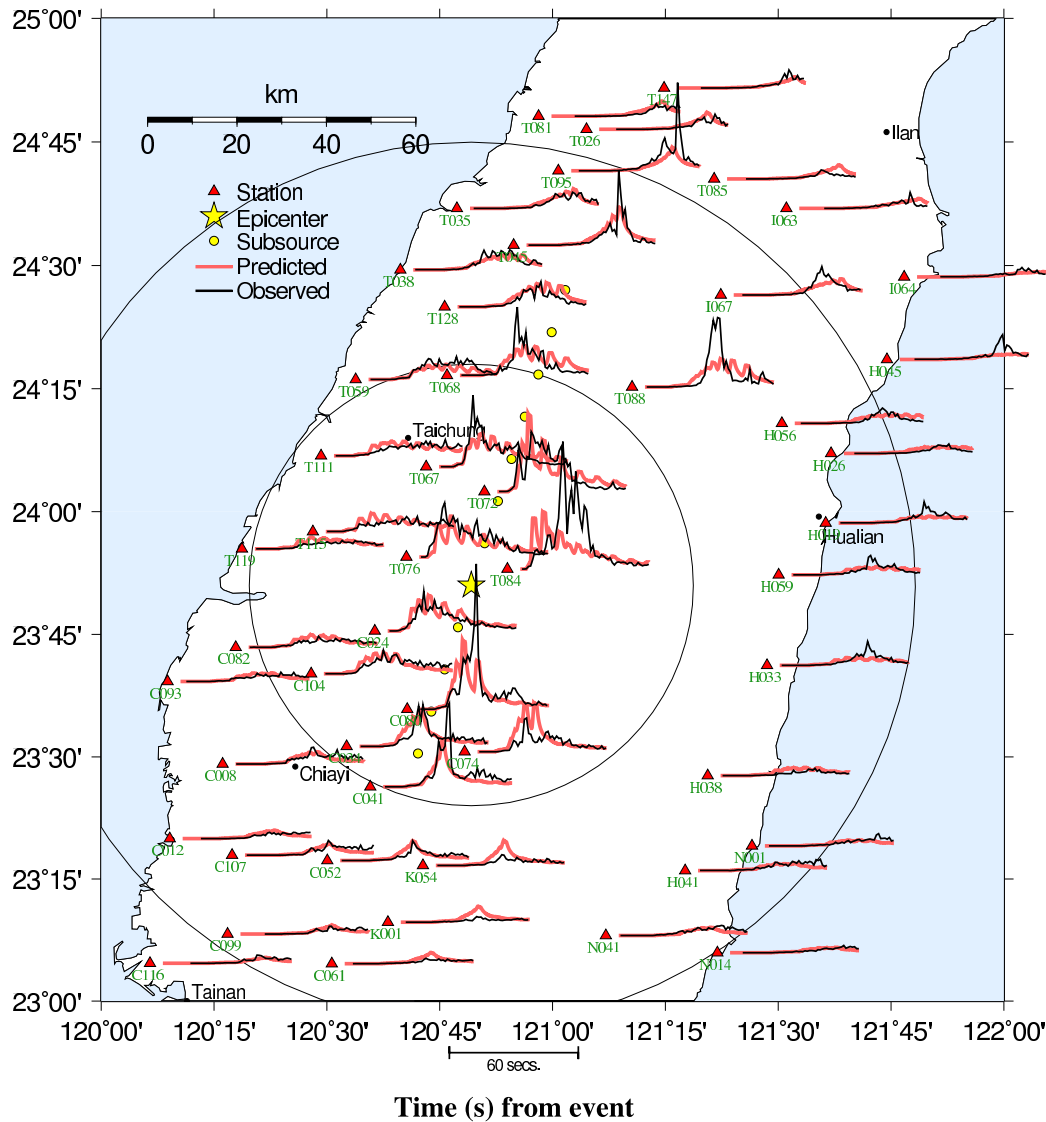

Figure 4.13: Predicted and observed envelopes in the horizontal component. The red and black lines are the predicted and observed envelopes, respectively. The locations of the subsources estimated from model 1 are shown in a small yellow circles. The area within 50 km and 100 km from the epicenter are shown by large circles. Only characteristic records of the stations are shown in this figure.

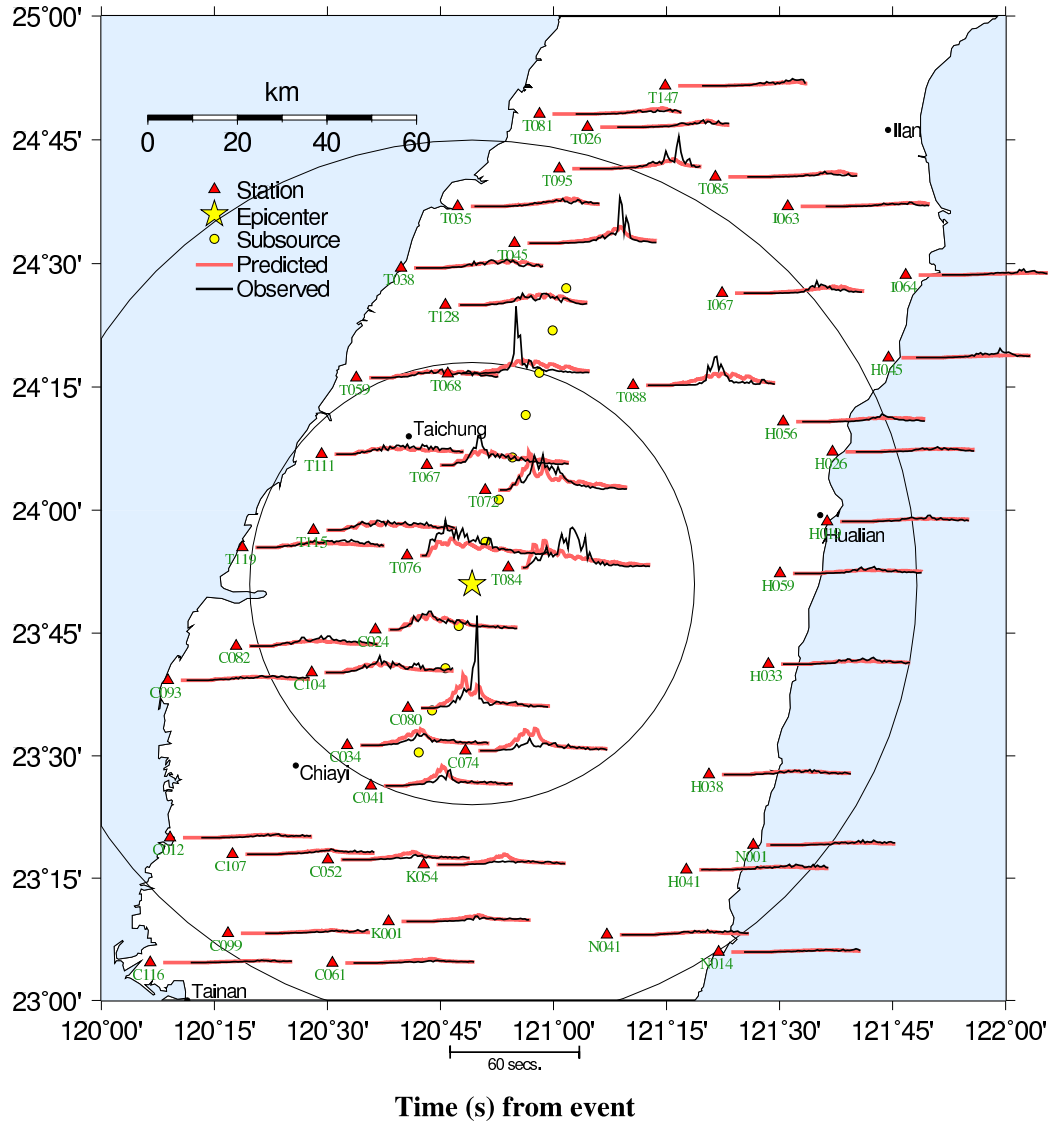

Figure 4.14: Predicted and observed envelopes in the vertical component. The symbols are in the same format as in figure 4.13.

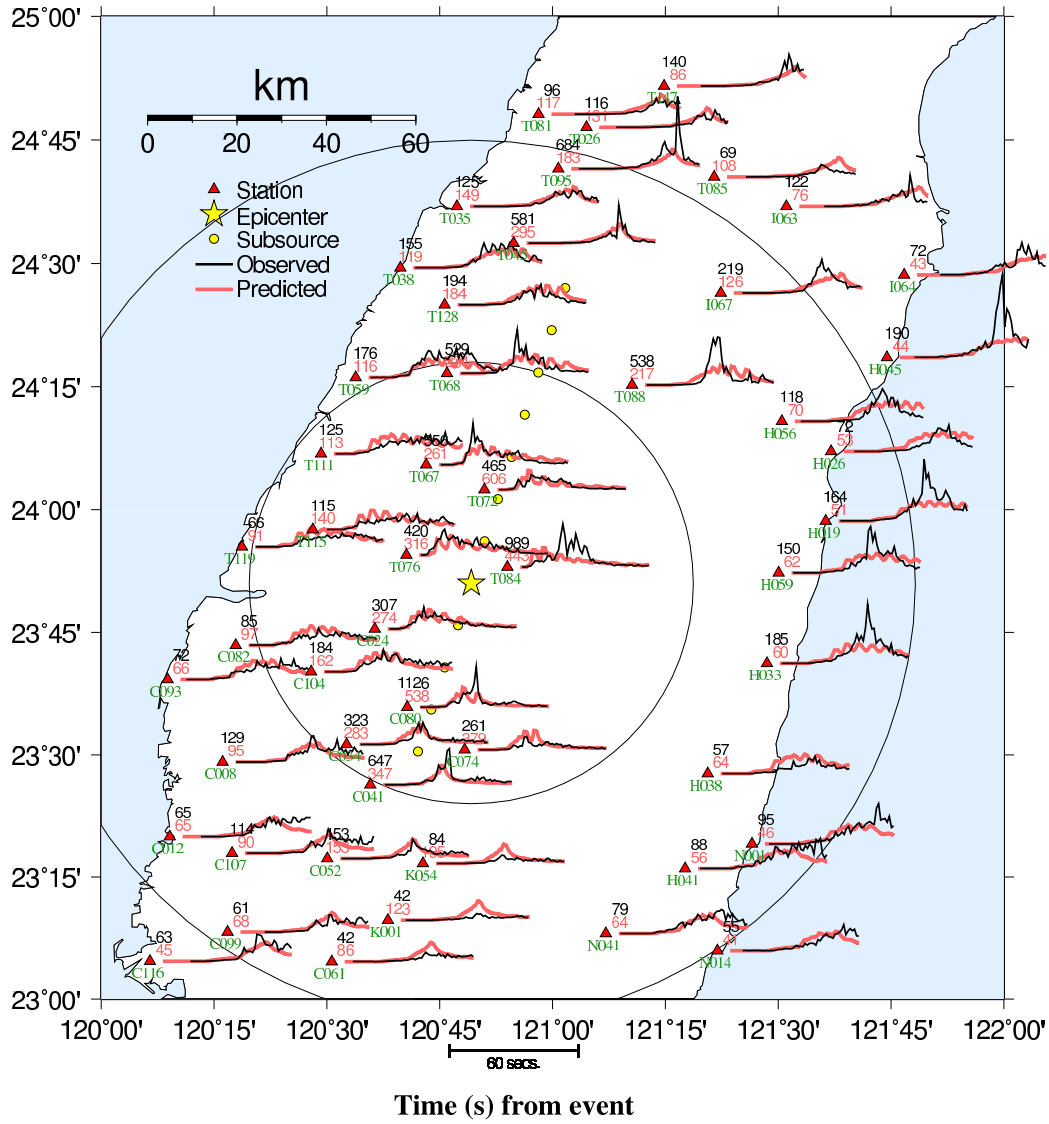

Figure 4.15: Predicted and observed envelopes in the horizontal component with different scaling. The waveforms are scaled so that the peak amplitude of the predicted envelopes becomes a unit length. The predicted and observed envelopes of the same station have the same scaling. The peak values are shown at the upper right of each station. The symbols are in the same format as in figure 4.13.

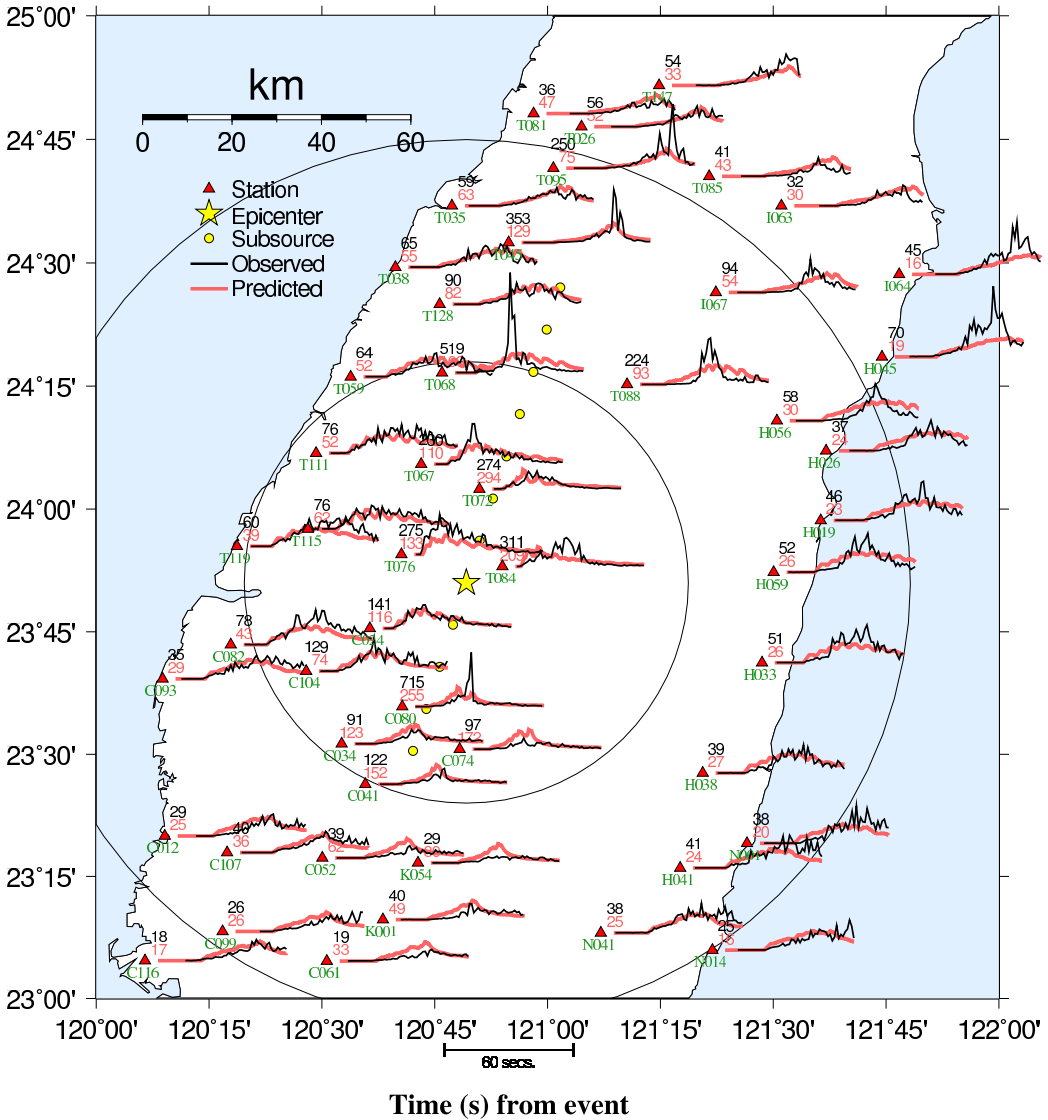

Figure 4.16: Predicted and observed envelopes in the vertical component with different scaling. The scalings are the same as in figure 4.15. The symbols are in the same format as in figure 4.13.

Figure 4.17: Enlarged map of figure 4.13. All of the stations near the epicenter are shown in this figure.

Figure 4.18: Enlarged map of figure 4.14. All of the stations near the epicenter are shown in this figure.

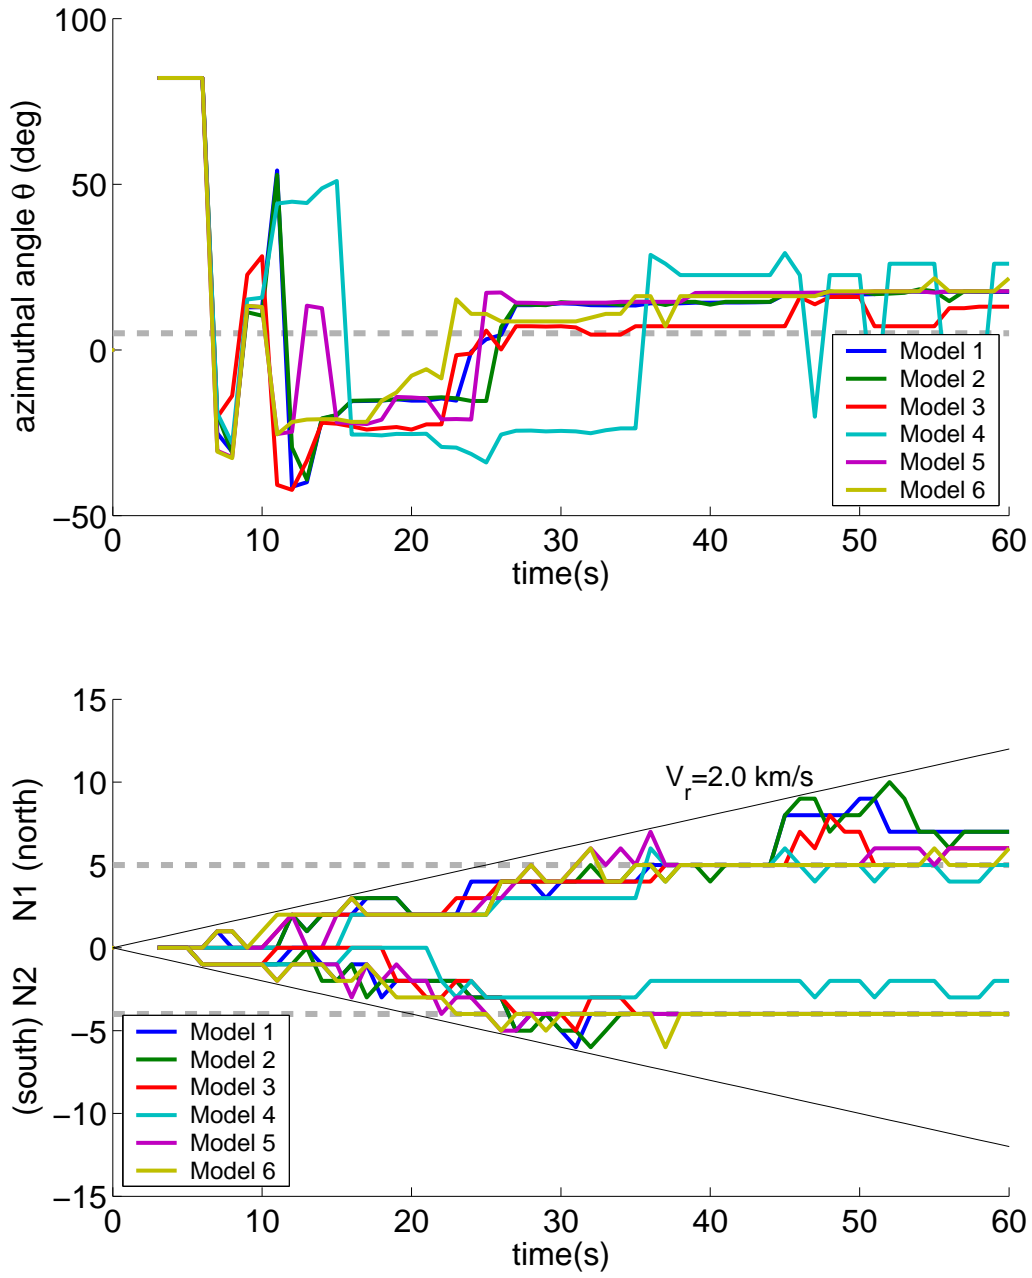

Figure 4.19: Time series of the estimated parameters,  $\theta$ , N1, and N2, for each model. The model numbers correspond to the numbers in table 4.2. Time is relative to the origin. The parameters are computed at each second using only the data available at that time. The broken lines are the best estimates based on the fault model proposed by Ji et al. (2003). Top: time series estimations for  $\theta$ . Bottom: time series estimations for N1 and N2. The solid thin lines are the upper limits for N1 and N2 for the rupture velocity 2 km/s.

Figure 4.19 shows the estimation results of three parameters (azimuthal angle of fault line ( $\theta$ ), number of the point sources to the north (N1) and to the south (N2)). Three parameters are computed at each second using only the data available at that time. The estimation is updated every second as the ground motion data are observed.

#### 4.3.3.1 Result of model 1 (horizontal and vertical data)

Model 1 includes all of the data considered in this study. Although it does a good job at characterizing the rupture length and timing, we see that it is difficult to resolve  $\theta$  until 15 seconds after the event onset since the event can be approximated as a point source at the beginning. The estimated  $\theta$  at 15 seconds is about -20 degrees and it increases gradually after 20 seconds due to a impulsive acceleration arrival at station C080 which is located at the south of the epicenter. Estimates of  $\theta$  stabilize at about 13 degrees with respect to additional data after 26 seconds. There is an additional small shift at 44 seconds, at which point the inversion achieves its final solution of 15 degrees, which compares favorably with the observed average fault strike of the Chelungpu fault rupture.

Since the subsources are equally spaced, the length of the fault is represented by the number of the point sources to the north (N1) and to the south (N2). Figure 4.19 (bottom) shows values of N1 and N2 as a function of time after the origin. From the figure, we can see the fault length grows bilaterally along the dashed black lines. At 26 seconds, the rupture stops growing to the south. It also stops to the north temporarily, but it grows again around 40 seconds. This is due to the delayed high-frequency radiation at stations north of the Chelungpu surface rupture and may have been caused by rupture on the Shihtan fault. Even though the result of the simulation fits the actual location of the fault accurately, the multiple source model does not consider “rupture jumping dislocations” (i.e., the rupture at the adjacent active faults triggered by the main shock) (Shin and Teng, 2001). The final result shows 7 point sources to the north and 4 point sources to the south. This fault length is comparable to the total length from the Chelungpu fault to the Shihtan fault in

figure 4.7.

#### 4.3.3.2 Result of model 2 (horizontal data) and model 3 (vertical data)

Model 2 only uses the horizontal acceleration data for the analysis whereas model 3 only uses the vertical acceleration data. The azimuthal angles of the fault for models 2 and 3 are not significantly different from model 1. The estimation of the angle, N1 and N2 from the horizontal component data (model 2) is similar to the estimation of model 1. However, the estimation of rupture length from the vertical component data (model 3) is a little smaller than that of model 1. In particular, the inversion indicates unilateral rupture to the north (i.e., N2 is zero) until 18 seconds after the origin. The reason is that the predicted envelopes overestimate the observed envelopes in the epicentral region for the first 10 seconds (see figure 4.14). Overall, the predicted envelope is larger than the observed envelope for the vertical component and smaller for the horizontal component.

#### 4.3.3.3 Result of model 4 (effect of area weight)

Model 4 considers the heterogeneity of station distribution and applies an area weight when we characterize the misfit function. The area weight is a coefficient applied for each station. Since the station distribution is not uniform for the Chi-Chi earthquake dataset, we attempt to normalize the effect of each station. We assume a station in a sparse area is more important than a station in a dense area. Therefore, when we compute the misfit function in equation 4.2, the misfit of each station is weighted by the area weight, which is proportional to the area of the Voronoi cell of each station (shown in figure 4.7).

There are quite a few differences between the estimates for N1 and N2 of model 1 and model 4. The real-time estimation of the azimuthal angle has unique characteristics. It stays around -20 degrees at the beginning of the rupture, and it jumps to 35 degrees suddenly at 36 seconds. The angle estimation is very unstable even after 40 seconds. Moreover, the estimate for N1 and N2 are a lot smaller than that of model 1. The reason for this sudden transition is that a few stations with large

area weighting (e.g., T088, T074, C074) control the parameters. When the envelopes of those stations are weighted, the residual sum of squares changes greatly, and the Neighborhood Algorithm chooses the parameter to reduce the residuals. We would like to obtain accurate information of the fault location as soon as possible. For this purpose, model 1 is more robust than model 4. In a larger sense though, it means that it becomes difficult to determine the fault geometry if the station distribution is sparse and uneven.

#### **4.3.3.4 Result of model 5 and model 6 (the effect of station distribution)**

In models 5 and 6, the effect of station distribution is examined further. To sample the stations randomly, we use the records with an even station code number for model 5. For model 6, the records with a station code ending in 6 or 8 (e.g., T078) are used. Even though the station distribution is not homogeneous as shown in figure 4.7, the average station density is  $214 \text{ km}^2/\text{station}$  for model 5, and  $482 \text{ km}^2/\text{station}$  for model 6. The stations are located in an area of about  $27,000 \text{ km}^2$ . Even though the station density is different, the estimated parameters are quite similar. In figure 4.19, the time series of  $\theta$  and N2 for models 1, 5, and 6 are almost the same. N1 for models 5 and 6 stays around 5 after 30 seconds, and the increase observed in Model 1 due to the Shihtan fault rupture does not appear. The reason is that several near-source stations of the Shihtan fault have an odd number station code and are not included in this analysis (e.g., T045, T047, and T095). Considering that the rupture of the Shihtan fault is quite small compared to that of the Chelungpu fault, model 5 and model 6 can express the Chi-Chi earthquake rupture well. The VS-FS method for large earthquakes works well even if the station density is reduced to a quarter of the original density, as long as the station distribution is uniform.

#### **4.3.4 Geometry of the parameter space**

We have solved the optimization problem in parameter space ( $\theta$ , N1, and N2) by a Neighborhood Algorithm. Here, we discuss the geometry of the parameter space.

Figure 4.20: Error surface of  $\theta$  and  $N1$  for Model 1 at the fixed  $N2 = 5$  at 60 seconds after the origin time. Since the surface is peaked around  $\theta = 0$ , it is easy to converge in  $\theta$ . However, the optimal  $N1$  will change easily depending on the misfit function (see equation 4.2).

Figure 4.20 shows the error surface of  $\theta$  and  $N1$  for model 1 at a fixed  $N2$  of 5 and assuming that all data is used in the inversion. The surface is smooth and has a deep and narrow valley at  $\theta = 10$ . The solution easily converges to this minimum. Figure 4.21 shows the error surface of  $N1$  and  $N2$  for model 1 at a fixed  $\theta$  of 10. The surface is very smooth in both  $N1$  and  $N2$  directions. The global minimum is very sensitive to the choice of the dataset, as shown in the results of model 5 and 6.

Contour maps of the error surface of  $N1$  and  $N2$  at 10 second intervals are shown in figure 4.22.  $\theta$  is fixed at 10 degrees which is the optimal final solution. At 10 seconds, the minimum of this error surface is  $(N1, N2) = (0, 1)$ . However, it is not the global minimum in the parameter space since  $\theta = 10$  is not the optimal solution at 10 seconds. At 20 and 30 seconds, the minimum of the error surface is at the maximum  $N1$  and  $N2$  in the possible parameter space even though  $\theta$  is not optimal.

Figure 4.21: Error surface of  $N1$  and  $N2$  for model 1 at the fixed  $\theta = 10$  at 60 seconds after the origin time. Since the surface is smooth in both  $N1$  and  $N2$  direction, the optimal solution is sensitive to a small disturbance.

There is high possibility that the rupture is still ongoing at this point. At 40 seconds, the minimum of the contour is around  $(N1, N2) = (6, 4)$  and it suggests that the rupture has stopped rupturing toward the south. After 40 seconds, the shape of contour map does not change much, and the elliptic shape of the smallest contour indicates that  $N2$  is determined uniquely, but that considerable uncertainty about  $N1$  remains.

The Neighborhood Algorithm generates samples in the parameter space and constructs the posterior probability density (ppd) from the ensemble samples. (In this simulation, the prior pdf is assumed to be uniform.) The 1-D marginal posterior ppd of parameter  $\theta$ ,  $N1$ , and  $N2$  are shown in are shown in figures 4.23 – 4.25. The ppd for  $\theta$  is more peaked than those for  $N1$  and  $N2$ , and it is consistent with the geometry of the error surface which enables a solution to converge easily to the minimum. The more data is available as the rupture propagates, the smaller the deviations of the ppd

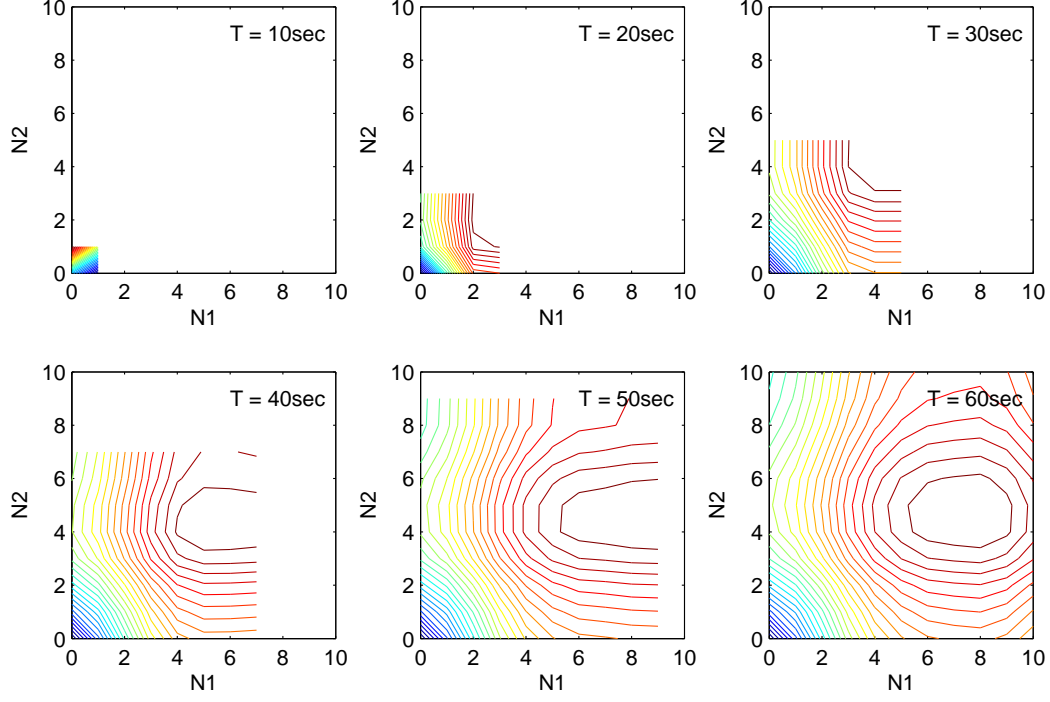

Figure 4.22: Contour maps of the error surface of  $N1$  and  $N2$  for model 1 at the fixed  $\theta = 10$ . The maps are shown in 10 second intervals. The blank area in the boxes is the region where there is no solution due to the constraint that the rupture velocity is less than 2 km/s.

becomes for all three parameters. Figure 4.26 is the 2-D marginal of parameters  $N1$  and  $N2$ . The difference between figure 4.22 and figure 4.26 is as follows: figure 4.22 is the error surface where the misfit function (equation 4.2) is evaluated and figure 4.26 is the posterior probability density of the parameter space. The location of the most probable solution is almost identical between figure 4.22 and 4.26, but figure 4.26 shows the ppd which represents the probability for each value of the parameters. The maximum value of ppd becomes larger with time.

Figure 4.23: Posterior probability for the parameter  $\theta$ .

Figure 4.24: Posterior probability for the parameter  $N1$ .

Figure 4.25: Posterior probability for the parameter N2.

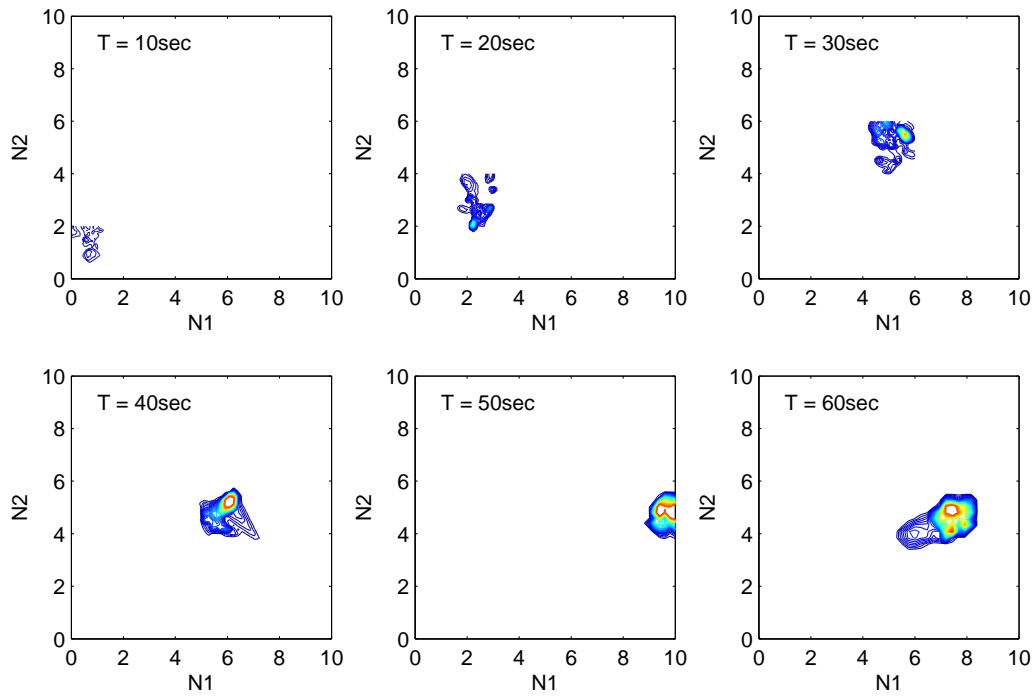

Figure 4.26: Two-dimensional posterior probability for the parameters N1 and N2. The plots are shown in 10-second intervals.

### 4.3.5 Effects of different misfit functions

In the course of this study, we also tried inversions in which we defined misfit function in terms of log of amplitudes and PGA. Figure 4.27 shows the simulation results with the same dataset as model 1 but different misfit functions. The misfit function used in the main analysis was:

$$RSS(t) = \sum_{i=1}^{ns} \sum_{j=1}^2 \sum_{k=1}^t (A_{ijk} - \hat{A}_{ijk})^2. \quad (4.3)$$

In the ground motion analysis, the distribution of log of amplitude follows the Gaussian distribution, so the log of amplitudes is often used as a misfit function. The misfit function in terms of log of amplitudes is:

$$RSS_{log}(t) = \sum_{i=1}^{ns} \sum_{j=1}^2 \sum_{k=1}^t (\log A_{ijk} - \log \hat{A}_{ijk})^2. \quad (4.4)$$

This misfit function emphasizes the ratio of predicted and observed amplitudes; large amplitude data is no more important than small amplitude data. However, we found that such a misfit function emphasized misfits in the coda for near-source data; furthermore, the distant data was often not well explained by our simple descriptions of wave envelopes that have been developed to explain the “average” effects of waves propagating through the crust. That is, it is important to emphasize the data from the near-source records and a logarithmic misfit function was not appropriate to recover the timing and location of the rupture.

We also tried the misfit function defined in terms of the error when the each ground motion records the peak value (PGA):

$$RSS_{max}(t) = \sum_{i=1}^{ns} \sum_{j=1}^2 (\max\{A_{ijk} | k = 1, \dots, t\} - \max\{\hat{A}_{ijk} | k = 1, \dots, t\})^2. \quad (4.5)$$

The fault length estimate from this misfit function is very unstable even after most of the rupture terminated. This is because far-source stations which receive propagating seismic waves with delay affect the misfit function. As we mentioned in the

Figure 4.27: Effects of different error functions. RSS error function gives the best estimate of the model parameters.

logarithmic misfit function, it is important to emphasize the data from the near-source records, and so the best estimate of the model parameters minimizes the RSS between observed ground motion envelopes and predicted envelopes from the multiple source model.

## 4.4 Summary

We outlined a strategy to estimate slip in time and space for an ongoing earthquake rupture. A key aspect of this strategy is to map the location of the rupture using envelopes of high-frequency acceleration data. Once the location of the rupture is estimated, long-period displacement data can be projected back onto the fault to determine the slip in real time.

Our strategy for using high-frequency radiation to determine the timing and length of the rupture relies on the observation that high-frequency seismic waves can be modeled as random-phase waves whose total radiated energy scales linearly with the rupture area. By using this assumption, we show that we can simulate the ground motion of a large earthquake by tiling the surface of the large event with smaller events and then summing the random phase signals from the smaller events. In our example of the Chi-Chi earthquake, we showed that a sum of 10 km interval magnitude 6.0 subevents provided a good prediction of the acceleration envelopes for this earthquake. In order to turn this simulation into a real-time inverse, we parameterize the rupture with a linear alignment of magnitude 6.0 earthquakes. We then invert for the azimuth angle of the alignment as well as two integers,  $N_1$  and  $N_2$ , which are the number of additional 10 km patches in the positive and negative directions from the epicenter, respectively.

The best estimate of the model parameters minimizes the residual sum of the squares between observed ground motion envelopes and predicted envelopes from the multiple source model (in equation 4.2). This misfit function with linear amplitudes of ground motions can provide better estimates than that of logarithmic amplitudes, since the linear misfit function tends to emphasize the importance of fitting stations with large amplitudes.

Our study of the Chi-Chi data set indicates that it is more difficult to determine rupture length than it is to determine rupture azimuth. Furthermore, for this method to work well, an adequate near-source station distribution is important. Real-time mapping of an on-going rupture using this strategy becomes a simple matter of

tracking the spatial evolution of near-source seismic stations. Although this strategy appears promising, it requires adequate station coverage to track near-source stations.

## Chapter 5

# Near-Source versus Far-Source Classification Analysis

We introduced the methodology that can estimate the rupture geometry from acceleration envelopes in the previous chapter. In this chapter, we propose another approach to recognize the fault rupture extent. We develop a methodology to classify stations into near-source and far-source by using the Bayesian model selection analysis so that we can identify the fault geometry if there is a sufficiently dense seismic network. Peak ground motions recorded in past earthquakes are analyzed to predict whether a station recording ground motion is close to the earthquake fault area. This classification problem can be stated as follows: given ground motion data from past earthquake records, what is the probability that a station is near-source when a new observation is obtained?

To approach this problem, we:

- 1) Collect strong motion data from earthquake strong motion archives and classify these samples into two predefined groups: records from near-source stations and far-source stations. This particular set of data is called the training set.
- 2) Discover a discriminant function of the samples features (e.g., peak ground acceleration (PGA), velocity (PGV), displacement (PGD)) which provides the best performance in terms of near-source versus far-source classification.
- 3) Allocate new observations when they are obtained to one of the two groups based on the discriminant function.

The first step is quite straightforward; strong motion data from past earthquakes are collected based on certain selection criteria. The second step is the main topic of this paper; and we investigate linear discriminant functions by using the traditional Fisher method and two Bayesian methods. The third step can then be accomplished in a real-time analysis. Given a new ground motion observation from on-going rupture, the discriminant function gives the probability that the observation is located in the near-source.

## 5.1 Strong motion data

We used strong motion datasets from nine earthquakes with magnitude greater than 6.0 and containing records of near-source stations. The selected earthquake dataset is shown in table 5.1. Here, we define a near-source station as a station whose fault rupture distance is less than 10km. 695 three-component strong motion data are used for the classification analysis and 14% (100 stations) are from near-source stations.

Table 5.1: The earthquake dataset used for the classification analysis. Moment magnitude ( $M_w$ ) is cited from Harvard CMT solution. The numbers of near-source (NS) and far-source (FS) data for each earthquake are also shown. The fault models are used as selection criteria to classify near-source and far-source stations.

### 5.1.1 Data sources

We obtained the strong motion dataset for the Imperial Valley (October 15, 1979), Loma Prieta (October 18, 1989), Landers (June 28, 1992), Northridge (January 17, 1994), and Denali (November 3, 2002) earthquakes from the COSMOS Virtual Data Center (<http://db.cosmos-eq.org>) which includes data from the California Strong Motion Instrumentation Program (CSMIP) seismic network and the United States Geological Survey (USGS) seismic network. The Northridge earthquake dataset in the COSMOS Virtual Data Center also includes records from seismic networks of the California Institute of Technology, Los Angeles Department of Water and Power, Metropolitan Water District, Southern California Earthquake Center, and University of Southern California. All these data were recorded by accelerometers and processed appropriately before distribution to users. The correction process may apply baseline corrections, band-pass filters to remove noise contamination, and instrument correction to remove the effects of frequency-dependent instrument response (<http://nsmg.wr.usgs.gov/processing.html>).

Strong motion data from the Hyogoken-nanbu earthquake (January 16, 1995) are provided by Japan Meteorological Agency (JMA), the Committee of Earthquake Observation and Research in the Kansai Area (CEORKA) in Japan (Toki et al., 1995), and the Japan Railway Institute (JR) whose records were scanned and digitized by Wald (1996). Seismometers installed in the CEORKA network record velocity, and those records are differentiated once to obtain accelerograms.

The national strong-motion accelerograph network in Turkey recorded the strong motions during the Izmit earthquake (August 17, 1999) (Akkar and Gülkan, 2002). They can be downloaded from the ftp site of the Earthquake Research Department of General Directorate of Disaster Affairs, Ministry of Public Works and Settlement, Ankara, Turkey (<ftp://angora.deprem.gov.tr/>). The COSMOS Virtual Data Center archived the dataset of another network operated by Kandilli Observatory and Earthquake Research Institute, Earthquake Engineering Department, Bogaziçi University, Istanbul, Turkey. Stations with fault distance greater than 200 km are excluded since

ground motion amplitudes of those stations are quite small which results in a low signal-to-noise ratio. We use four digital and six analog acceleration records from the national network and eight digital acceleration records from the Bogaziçi University network.

The Chi-Chi earthquake (September 20, 1999) is one of the best recorded earthquakes with a large number of stations and a dense station distribution both in the near-source and far-source. Strong motion records for the Chi-Chi earthquake are available on the attached CD in the Special Issue of the *Bulletin of the Seismological Society of America*, vol. 93, no. 5 (Lee et al., 2001). These records were produced by the Central Weather Bureau Seismic Network (CWBSN) and they are the largest set of strong motion data recorded from a major earthquake (Shin and Teng, 2001). Shin and Teng (2001) classified the recorded accelerograms into four quality groups based on the existence of absolute timing, pre-events, and defects. For this analysis, QA-class data (best for any studies) and QB-class data (next best but no absolute timing) are used.

Strong motion data from the Niigataken-chuetsu earthquake (October 23, 2004) were recorded by the K-NET and KiK-net seismic networks operated by the National Research Institute for Earth Science and Disaster Prevention in Japan. Those data are available at their websites (<http://www.k-net.bosai.go.jp/> and <http://www.kik.bosai.go.jp/>). The stations with epicentral distance less than 100 km are used for this analysis.

### 5.1.2 Data processing

We processed the accelerograms obtained from the nine earthquakes according to the following method. The DC offset of the accelerograms is corrected by subtracting the mean of the pre-event portion. Because a small DC offset has a large effect when the record is integrated, this process is applied to all accelerograms.

The peak amplitude of the horizontal components is calculated by the square root of the sum of the squares of the peaks of NS and EW components. If one of

the horizontal components (NS or EW) of a station has been clipped or is not well recorded, the square root of twice the other well-recorded horizontal component is used for the peak amplitude of the horizontal component.

The peak amplitude of UD (up-down) component is used directly for the peak vertical component. The station records that have defects in the vertical component are excluded.

The following processes are completed for all the data.

**Jerk:** The three-component accelerograms are differentiated in the time domain, using a simple finite-difference approximation. The peak value of each component is selected.

**Acceleration:** Original accelerograms are used to select the peak value.

**Velocity:** Some velocity records have a linear trend due to either tilting, the response of the transducer to strong shaking, or problems in the analog-to-digital converter. The baseline correction scheme applied to obtain appropriate velocity records is as follows (Iwan et al., 1985; Boore, 2001):

1) Determine the straight line to be subtracted from the velocity trace. The line is given by the equation:

$$v_f(t) = a_1 t + a_2, \quad (5.1)$$

where coefficients  $a_1$  and  $a_2$  are determined by least-squares fitting to the velocity trace after the strong shaking. The segment of the record used for least-squares fitting is from  $t_1$  to  $t_2$  (see figure 5.1).  $t_1$  is the time when the strong shaking has subsided. The results of baseline correction are not very sensitive to the choice of  $t_1$  (Boore, 2001). The second cut-off time,  $t_2$ , is generally chosen as the end of the record;

2) Remove this linear trend from the velocity record.

This baseline correction scheme assumes the baseline shift of the acceleration occurs only once. There may be records that have more than one baseline shift during strong shaking. However, our purpose is to get the peak value of each velocity

record, and this does not require accurate integration of the entire record. After time-domain integration, the distortion is not very large in the first portion of the record where the peak value is generally recorded.

Figure 5.1: An example of baseline correction for a velocity record from the Chi-Chi earthquake. The corrected velocity trend is obtained by subtracting the linear trend from the original velocity record. The portion of the record from  $t_1$  to  $t_2$  is used for least-square fitting to obtain the linear trend.

**Displacement:** The corrected velocity records are integrated once in the time domain and high-pass filtered using a fourth-order Butterworth filter with a corner frequency of 0.075 Hz.

The peak features used for the classification analysis are shown in table 5.2. Several combinations of these 8 features are tried to find the best performance of the classification.

### 5.1.3 Data classification

The classification as near-source or far-source in the training set is based on rupture area models used for waveform inversions. These rupture area models are typically determined from the aftershock distribution (Sekiguchi et al., 1996), and the shape

Table 5.2: Eight measurements of peak ground motions are calculated from three component accelerograms. Codes and units of the components used in this paper are shown.

Code	Measurement	Unit
Hj	Horizontal Peak Ground Jerk	(cm/s <sup>3</sup> )
Zj	Vertical Peak Ground Jerk	(cm/s <sup>3</sup> )
Ha	Horizontal Peak Ground Acceleration	(cm/s <sup>2</sup> )
Za	Vertical Peak Ground Acceleration	(cm/s <sup>2</sup> )
Hv	Horizontal Peak Ground Velocity	(cm/s)
Zv	Vertical Peak Ground Velocity	(cm/s)
Hd	Horizontal Peak Ground Displacement	(cm)
Zd	Vertical Peak Ground Displacement	(cm)

of the rupture area is approximated by a rectangular box. Fault models used for classifying stations are shown in table 5.1 and figure 5.2. In figure 5.2, black solid lines indicate the surface projection of the fault rupture surface based on the fault models. Stations within 10 km of this fault projection (the white area in the figures) are classified as near-source, indicated by solid circles. Far-source stations are shown in open circles.

High-frequency near-source ground motions have long been researched by engineers and seismologists. High-frequency ground motions depend weakly on magnitude in the near-source (Hanks and Johnson, 1976; Joyner and Boore, 1981; Hanks and Mcguire, 1981). This helps to analyze ground motions with a wide range of magnitudes. Figure 3.2 shows horizontal and vertical PGA of near-source records in our training set as a function of moment magnitude. The slope of a regression line would be almost equal to zero, which is consistent with past studies. On the other hand, low-frequency motion has a strong correlation with magnitude. Figure 3.4 shows horizontal and vertical PGD as a function of moment magnitude. The PGD are log proportional to the magnitude. Based on such observations, we assume that high-frequency motion does not depend on magnitude for large earthquake and that accelerations do not exceed 2g, whereas low-frequency motion is highly correlated with magnitude, and its amplitude increases as the magnitude becomes large.

Figure 5.2: Maps of the fault projections and station distributions (continued).

High-frequency ground motion decays in amplitude more rapidly with distance than low-frequency motion (Hanks and McGuire, 1981). Therefore, high-frequency motions (e.g., acceleration, jerk) have high correlations with the fault distance. We compute the log of the ground motion amplitudes and find the means and standard deviations for the near-source and far-source records. Figure 5.3 shows the histograms

and Gaussian densities given by the sample means and standard deviations for the near-source and far-source records. The Gaussian densities are good approximations of the histograms of the log of the ground motion data. Figure 5.3 also shows that the distance between means for the near-source and far-source datasets is larger in high-frequency than low-frequency motions. Therefore, we expect that the high-frequency motions is a good measure to classify near-source and far-source records.

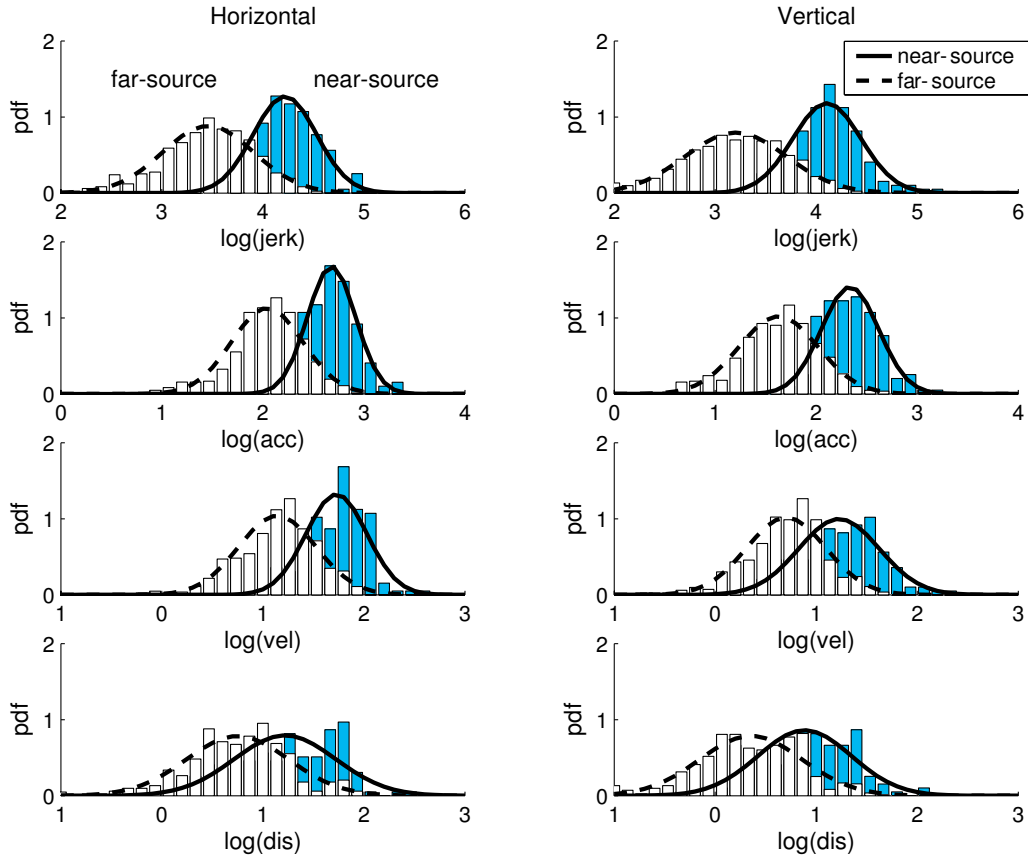

Figure 5.3: Histograms and Gaussian densities based on the sample means and standard deviations of the log of ground motions for the near-source and far-source records. These are distributions for jerk, acceleration, velocity, and displacement from the top.

## 5.2 Near-source versus far-source discriminant function

We assume the discriminant function to classify records into near-source and far-source is expressed as a linear combination of the log of ground motion amplitudes:

$$\begin{aligned}
 f(X_i|\theta) &= c_1 x_{i1} + c_2 x_{i2} + \dots + c_m x_{im} - d \\
 &= \sum_{k=1}^m c_k x_{ik} - d \\
 &= X_i \cdot c - d,
 \end{aligned} \tag{5.2}$$

where

$x_{ik}$  =  $k$ th feature parameter of the ground motion at the  $i$ th station,

$m$  = the number of feature parameters,

$X_i = [x_{i1}, x_{i2}, \dots, x_{im}]$

$= [\log_{10}(\text{component1}), \log_{10}(\text{component2}), \dots, \log_{10}(\text{componentm})]$ ,

$c_1, \dots, c_m$  = the regression coefficients,

$d$  = decision boundary constant,

$\theta = [c_1, c_2, \dots, c_m, d]^T$ .

We may use  $m$  components out of the eight ground motion components shown in table 5.2. The coefficients  $c_1, \dots, c_m$ , and  $d$  are determined from the training data set by two different approaches: Fisher's linear discriminant analysis and Bayesian analysis.

This discriminant function is used to allocate new observations to one of the near-source or far-source groups, where  $f(X_i|\theta) = 0$  is the boundary between the two groups in the feature parameter space. The station with observation  $X_i$  is classified as near-source if  $f(X_i|\theta)$  is positive. If  $f(X_i|\theta)$  is negative, the station is classified as a far-source station. Note that the decision boundary may also be expressed using

equation 5.2 as:  $X_i \cdot c = d$ .

### 5.2.1 Fisher's linear discriminant analysis

Fisher's Linear Discriminant Analysis (LDA) is a method to classify data by using a linear function (5.2) that best discriminates two or more naturally occurring groups. LDA was first described by Fisher (1936) to separate two groups optimally. In general, LDA requires placing objects (e.g., humans) in predefined groups (e.g., Caucasoid, Mongoloid, and Negroid) based on certain feature parameters (e.g., related to physical characteristics), and finding a function to distinguish the groups. The parameters  $c_k$  in the linear function (5.2) are selected to minimize the within-group variance (variance of the samples centered on the group mean) and maximize the between-group variance (variance between group means). The following is a brief discussion about the procedure of linear discriminant analysis (Venables and Ripley, 2002):

Consider  $n \times m$  data matrix  $X$  where  $n$  is the number of samples and  $m$  is the number of different features of samples. Each sample is assigned to one of  $g$  groups  $N_j, j = 1, \dots, g$ , with  $n_j$  observations in each group. Let  $G$  denote the group indicator matrix, which indicates the group each sample is assigned to, and let  $M$  denote the group mean matrix, then within-group covariance matrix  $W$  and between-group covariance matrix  $B$  are:

$$W = \frac{(X - GM)^T(X - GM)}{n - g}, \quad (5.3)$$

$$B = \frac{(GM - \mathbf{1}\mu)^T(GM - \mathbf{1}\mu)}{g - 1}, \quad (5.4)$$

where

$X = [x_{ik}] : n \times m$  data matrix,

$G = [g_{ij}] : n \times g$  group indicator matrix,

$M = [m_{jk}] : g \times m$  group mean matrix,

$\mu = [\mu_1, \mu_2, \dots, \mu_m] : 1 \times m$  mean vector,

$\mathbf{1} = n \times 1$  column vector of 1s,

$x_{ik}$  =  $k$ th feature of the  $i$ th sample,

$g_{ij} = 1 \iff X_i = [x_{i1}, x_{i2}, \dots, x_{im}]$  is assigned to group  $j$ ,

$$m_{jk} = \frac{1}{n_j} \sum_{i \in N_j} x_{ik},$$

$$\mu_k = \frac{1}{n} \sum_{i=1}^n x_{ik}.$$

We would like to find a linear combination  $X \cdot c$  of the data such that the different groups are maximally separated, that is, maximizing the following separation ratio  $\lambda$ :

$$\lambda = \frac{c^T B c}{c^T W c} = \frac{\text{between-group variance}}{\text{within-group variance}}. \quad (5.5)$$

A necessary condition to maximize  $\lambda$  is  $\frac{\partial \lambda}{\partial c} = 0$ . By substituting equation 5.5 into this condition, we get:

$$W^{-1} B c = \lambda c, \quad (5.6)$$

assuming  $W$  is invertible. This is an eigenvalue problem, and the weight vector  $c$  and the separation ratio  $\lambda$  are eigenvectors and eigenvalues of  $W^{-1} B$ , respectively.  $X \cdot c$  is called a canonical variate, and the canonical variate of the eigenvector  $c$  which corresponds to the largest eigenvalue is called the first canonical variate.

For the near-source versus far-source classification problem, the data matrix  $X$  is the dataset of peak seismic ground motions, where  $n$  is the number of stations, and  $m$  is number of the object features (PGA, PGV, PGD, etc.). We have two groups: near-source group and far-source group ( $g = 2$ ). LDA finds the optimal set of coefficients of ground motion amplitudes to classify near-source or far-source records.

Since the traditional LDA does not treat which choice of the ground motion parameters is the best, Bayesian model class selection is performed (the results are shown later). According to this analysis, the best selection is (Za and Hv), and their coefficients obtained from LDA are shown in table 5.3.

Table 5.3: Estimated model parameters by Fisher's LDA, Bayesian approach with asymptotic approximation, and Bayesian approach with the Metropolis algorithm. The standard deviations for each parameter are shown in brackets.

Method	$c_1$ (Za)	$c_2$ (Hv)	$d$
LDA	7.233	6.813	25.903
Bayesian-Asym. ( $\sigma$ )	6.046 ( $\pm 0.903$ )	7.886 ( $\pm 1.206$ )	27.090 ( $\pm 3.163$ )
Bayesian-MA ( $\sigma$ )	6.194 ( $\pm 0.946$ )	8.150 ( $\pm 1.224$ )	27.872 ( $\pm 3.330$ )

We choose the decision boundary constant  $d$  to maximize the classification performance for the set of coefficients obtained by the LDA. The classification performance is evaluated by the following function:

$$P_c(d) = (P(f(X_i|\theta) \geq 0 | Y_i = 1) + P(f(X_i|\theta) < 0 | Y_i = -1))/2, \quad (5.7)$$

where

$$f(X_i|\theta) = X_i \cdot c - d,$$

$$Y_i = \begin{cases} 1 & \text{if near-source,} \\ -1 & \text{if far-source.} \end{cases}$$

This is the average probability between the probability that a near-source station is classified correctly and the probability that a far-source is classified correctly. The parameter  $d$  which maximizes this function for the given coefficients (table 5.3) is 25.903, and the performance defined by the function above is 93.4%. Another way to compute  $d$  is to take the midpoint of the two group means of the first canonical variate. This method makes it easier to compute the value of  $d$  and it gives  $d = 25.045$ , a good approximation to  $d = 25.903$  which shows maximum performance.

As a conclusion, the discriminant function computed from the LDA is:

$$f(X_i|\theta) = 7.233 \log_{10} Za + 6.813 \log_{10} Hv - 25.903, \quad (5.8)$$

$$\text{if } \begin{cases} f(X_i|\theta) \geq 0 & \text{near-source,} \\ f(X_i|\theta) < 0 & \text{far-source.} \end{cases}$$

This discriminant function is applied to all the dataset, and the values of  $f(X_i|\theta)$  are shown in figure 5.4. The figure shows that most of the near-source data lie on the right side of the decision boundary, which means the classification performance is very good.

### 5.2.2 Bayesian approach

In this section, a Bayesian approach is applied to determine the coefficients of the discriminant function that classifies near-source and far-source data. The probability density function (pdf) of parameter  $\theta$  conditioned on data  $D_n$  and model class  $M$  can be expressed using Bayes' theorem:

$$\begin{aligned} p(\theta|D_n, M) &\underset{\text{posterior}}{\propto} \underset{\text{likelihood}}{p(D_n|\theta, M)} \times \underset{\text{prior}}{p(\theta|M)} \\ &\propto \prod_{i=1}^n P(Y_i|X_i, \theta) \times p(\theta|M), \end{aligned} \quad (5.9)$$

Figure 5.4: Histogram of the near-source and far-source data to which the discriminant function obtained from traditional LDA is applied. The column heights are normalized by the number of the data in each group.  $f(X_i|\theta) = 0$  is the decision boundary between the two groups. The curves are the Gaussian distribution with the same mean and standard deviation as the values of  $f(X_i|\theta)$  for each group.

where

$\theta = [c_1, c_2, \dots, c_m, d]^T$  : parameter vector,

$D_n = \{(X_i, Y_i) : i = 1, \dots, n\}$  : available set of data,

$X_i = [x_{i1}, x_{i2}, \dots, x_{im}]$  : ground motion at the station  $i$

$= [\log_{10}(\text{component1}), \log_{10}(\text{component2}), \dots, \log_{10}(\text{componentm})]$ ,

$Y_i = \begin{cases} 1 & ; \text{ if near-source} \\ -1 & ; \text{ if far-source} \end{cases}$  at the station  $i$ ,

$m$  = the number of object features,

$n$  = the number of data.

Note that the model class  $M$  defines the likelihood for each value of  $\theta$  in some set of values and also the prior pdf  $p(\theta)$ .

We determine the parameters  $c_1, \dots, c_m, d$  based on a Bayesian approach using the same notation as the LDA. The goal of the Bayesian approach is to obtain the posterior pdf of the model parameters ( $\theta$ ) and determine the most plausible value of  $\theta$  by maximizing this pdf.

### Choice of Prior Distribution

Assume that the model class  $M$  is globally identifiable based on  $D_n$  (Beck and Katafygiotis, 1998), that is, there is a unique  $\theta$  maximizing the likelihood  $p(D_n|\theta, M)$ . In this case, given a sufficiently large dataset  $D_n$ , the choice of prior pdf does not affect the resulting posterior pdf, and all posteriors with different priors will converge to the same answer (Sivia, 1996). Here, the prior is chosen to cover a wide range of the parameter space by selecting the prior of each model parameter to be a Gaussian pdf with zero mean and standard deviation  $\sigma=100$ , so:

$$p(\theta|M) = \frac{1}{(\sqrt{2\pi}\sigma)^{m+1}} \exp\left(-\frac{1}{2\sigma^2}\theta^T\theta\right) = \frac{1}{(\sqrt{2\pi}\sigma)^{m+1}} \exp\left(-\frac{1}{2\sigma^2}\left(\sum_{k=1}^m c_k^2 + d^2\right)\right). \quad (5.10)$$

### Choice of Likelihood function

Let the predictive probability that station  $i$  is near-source be  $P(Y_i = 1|X_i, \theta)$ . The predictive probability that a station is far-source is then  $P(Y_i = -1|X_i, \theta) = 1 - P(Y_i = 1|X_i, \theta)$ . A standard approach in Bayesian classification is to define the predictive probability by applying the logistic sigmoid function  $\phi(x) = 1/(1 + e^{-x})$  to the linear function  $f(X_i|\theta)$  that is also used in the traditional LDA (Li et al., 2002). The logistic sigmoid function is a smooth, positive, and monotonically increasing function, as shown in figure 5.5. The predictive probability that the  $i$ th station is near-source is therefore defined here by:

$$P(Y_i = 1|X_i, \theta) = \phi(f(X_i|\theta)) = \frac{1}{1 + e^{-f(X_i|\theta)}}. \quad (5.11)$$

Figure 5.5: Logistic sigmoid function  $\phi(x) = 1/(1 + e^{-x})$  is used to express the predictive probability for classification. The function approaches zero as  $x \rightarrow -\infty$ , and one as  $x \rightarrow \infty$ . The function is 0.5 when  $x$  is zero.

As  $f(X_i|\theta)$  becomes larger, the station is more likely to be near-source, and the probability that the station is near-source becomes closer to one. Note that the predictive probability that the station is far-source is then:

$$P(Y_i = -1|X_i, \theta) = 1 - \phi(f(X_i|\theta)) = \phi(-f(X_i|\theta)) = \frac{1}{1 + e^{f(X_i|\theta)}}, \quad (5.12)$$

where, from equation 5.2,

$$f(X_i|\theta) = \sum_{k=1}^m c_k x_{ik} - d = X_i \cdot c - d.$$

From equations 5.11 and 5.12, the likelihood function can be expressed as:

$$p(D_n|\theta, M) = \prod_{i=1}^n P(Y_i|X_i, \theta) = \prod_{i=1}^n \phi(Y_i f(X_i|\theta)) = \prod_{i=1}^n \frac{1}{1 + e^{-Y_i f(X_i|\theta)}}. \quad (5.13)$$

## Posterior Distribution

By substituting equations 5.10 and 5.13 into equation 5.9, the posterior can be expressed as:

$$p(\theta|D_n, M) \propto \frac{1}{(\sqrt{2\pi}\sigma)^{m+1}} \exp\left(-\frac{1}{2\sigma^2}\theta^T\theta\right) \prod_{i=1}^n \frac{1}{1 + e^{-Y_i f(X_i|\theta)}}. \quad (5.14)$$

Both an asymptotic approximation and stochastic simulation are performed to characterize the pdf defined by equation 5.14. In the asymptotic approach, the posterior is represented by a Gaussian distribution for  $\theta$  with mean  $\hat{\theta}$ , the most probable value of  $\theta$ , and a covariance matrix  $\hat{\Sigma}$  defined later. Stochastic simulation uses the Metropolis algorithm to generate random samples of the parameter vector  $\theta$  from the posterior pdf. It is noted that it is computationally challenging to evaluate the proportionality constant in equation 5.14 that normalizes the posterior pdf because it requires numerical integration over a high-dimensional parameter space. However, this evaluation can be avoided in both the asymptotic approximation and stochastic simulation methods.

### 5.2.2.1 Asymptotic approximation

We first find the optimal value  $\hat{\theta}$  of  $\theta$  that maximizes the posterior pdf. This multidimensional optimization problem is solved by a numerical optimization algorithm provided by Matlab.

Using Laplace's method of asymptotic approximation, Beck and Katafygiotis (1998) show that the posterior pdf for a set of model parameters  $\theta$  for a globally identifiable model class  $M$  (which has a unique most probable value) may be approximated accurately by a Gaussian distribution with mean  $\hat{\theta}$  and covariance matrix  $\hat{\Sigma}$ , given a large amount of data. Define  $H(\theta)$  by:

$$H(\theta) = -\nabla\nabla \log[p(D_n|\theta, M)p(\theta|M)] = -\nabla\nabla \log\left[\prod_{i=1}^n P(Y_i|X_i, \theta)p(\theta|M)\right], \quad (5.15)$$

then  $\hat{\Sigma} = H(\hat{\theta})^{-1}$ . By substituting equations 5.10 and 5.13 into equation 5.15;

$$\begin{aligned}
[H(\theta)]_{(\alpha,\beta)} &= [-\nabla\nabla \log \prod_{i=1}^n P(Y_i|X_i, \theta) - \nabla\nabla \log p(\theta|M)]_{(\alpha,\beta)} \\
&= -\frac{\partial^2}{\partial c_\alpha \partial c_\beta} (\log \prod_{i=1}^n \phi_i) + \frac{1}{\sigma^2} \delta_{\alpha\beta} \\
&= -\sum_{i=1}^n \frac{\partial^2}{\partial c_\alpha \partial c_\beta} (\log \phi_i) + \frac{1}{\sigma^2} \delta_{\alpha\beta} \\
&= -\sum_{i=1}^n \frac{\partial}{\partial c_\beta} \left[ \frac{1}{\phi_i} \phi_i (1 - \phi_i) \frac{\partial(Y_i f(X_i|\theta))}{\partial c_\alpha} \right] + \frac{1}{\sigma^2} \delta_{\alpha\beta} \\
&= \sum_{i=1}^n \phi_i (1 - \phi_i) x_{i\alpha} x_{i\beta} + \frac{1}{\sigma^2} \delta_{\alpha\beta}, \tag{5.16}
\end{aligned}$$

where  $\phi_i = \phi(Y_i f(X_i|\theta))$ , and equation 5.2, along with  $Y_i^2 = 1$ , has been used. The optimal parameter values and their standard deviations for the selection of features Za and Hv are shown in table 5.3. Note that for large  $\sigma$ , the effect of the prior in equation 5.16 is negligible.

In order to examine the sensitivity of the Bayesian approach to the training dataset, we perform a cross-validation analysis. First, the training dataset is randomly divided into two datasets and the discriminant function is constructed from one dataset (training set). This discriminant function is applied to the other dataset (validation set) to check its classification performance. We then switch the testing set and validation set, and repeat this cross-validation analysis. We set the near-source versus far-source boundary so that the probability is a half that the station is near-source, that is, the station is classified as near-source if the probability that it is near-source is more than  $1/2$ . The confusion matrices of these two analysis and the previous analysis which uses all of the dataset are shown in table 5.4. The classification error with half of the dataset is as small as that of the analysis which uses all of the dataset. Therefore, we confirm that the sensitivity to the training dataset is small, giving more confidence that the discriminant function from Bayesian analysis will perform well for future earthquake data.

Table 5.4: The confusion matrix for the cross-validation analysis with the Bayesian method with asymptotic approximation. “All dataset” is the analysis which uses the whole dataset as a training set and a validation set. “Half of dataset” is the analysis which uses half of dataset as a training set and the other half as a validation set. “Other half of dataset” is the analysis which switches the training and validation set. NS and FS stand for near-source and far-source, respectively.

Dataset	NS/FS	Near-source	Far-source
All dataset	NS	78 (78%)	22 (22%)
	FS	12 (2%)	583 (98%)
Half of dataset	NS	39 (74%)	14 (26%)
	FS	4 (1%)	291 (99%)
Other half of dataset	NS	37 (79%)	10 (21%)
	FS	8 (3%)	292 (97%)

### 5.2.2.2 Stochastic simulation using Metropolis algorithm

The asymptotic approximation is valid only if the posterior pdf for the model parameters can be approximated well with a Gaussian distribution. This requires a large sample size and that the class of models  $M$  is globally identifiable based on data  $D_n$  (Beck and Katafygiotis, 1998). On the other hand, a stochastic simulation algorithm can be applied to the problem which generates samples from a Markov Chain whose stationary pdf is the posterior pdf, that is, the samples are asymptotically distributed according to the posterior pdf for the parameters. The Metropolis algorithm is used to solve this high-dimensional problem, because it does not require evaluation of the normalizing constant for sampling the posterior pdf in equation 5.14.

The Metropolis algorithm is a Markov chain Monte Carlo (MCMC) method proposed by Metropolis et al. (1953). It is a simulation technique for generating random samples from any given probability distribution. The algorithm uses a proposal pdf  $Q$  which depends on the current sample of parameters,  $\theta^{(t)}$  at  $t$ th iteration (MacKay, 1999). Here, we choose as the proposal density a Gaussian pdf centered on the current parameters  $\theta^{(t)}$  with the covariance matrix  $\Sigma$  of the parameters in the asymptotic approximation. The optimal parameters estimated from direct optimization of the

posterior pdf are used as an initial  $\theta^{(t)}$ . The expression for  $Q$  is:

$$Q(\theta'|\theta^{(t)}) = \frac{1}{(2\pi)^{m'/2}|\Sigma|^{1/2}} \exp\left(-\frac{1}{2}(\theta' - \theta^{(t)})^T \Sigma^{-1}(\theta' - \theta^{(t)})\right), \quad (5.17)$$

where  $|\Sigma|$  is the determinant of the covariance matrix, and  $m'$  is the dimension of the parameter  $\theta$ , which is  $m + 1$ . A candidate sample is drawn from  $Q(\theta'|\theta^{(t)})$ . The ratio of the posterior pdf in equation 5.9 at the current sample  $\theta^{(t)}$  and the candidate sample  $\theta'$  determines whether to accept the candidate sample, according to:

$$r = \frac{p(\theta'|D_n, M)}{p(\theta^{(t)}|D_n, M)}, \quad (5.18)$$

$$\theta^{(t+1)} = \begin{cases} \theta' & \text{with probability } \min(1, r), \\ \theta^{(t)} & \text{with probability } 1 - \min(1, r). \end{cases} \quad (5.19)$$

If  $r \geq 1$  then the candidate is accepted as the next sample in the Markov Chain. Otherwise, the candidate is accepted with probability  $r$  as follows; we generate a random number uniformly distributed between zero and one, and if it is less than  $r$ , the candidate is accepted, that is,  $\theta^{(t+1)} = \theta'$ . If it is not accepted, the current sample is repeated ( $\theta^{(t+1)} = \theta^{(t)}$ ). This procedure is repeated until the desired number of samples are generated. There is a burn-in period at the beginning of the MCMC method until the probability distribution of the current sample  $\theta^{(t)}$  is sufficiently close to the posterior pdf, which is the stationary pdf of the Markov chain, so judgment is used to discard initial samples.

Figure 5.6 shows 5000 parameter samples generated with the Metropolis algorithm for the optimal selection of features  $Z_a$  and  $H_v$ . This selection of the ground motion features comes from Bayesian model class selection explained later. After discarding the samples in the burn-in period (taken as the first 100 samples), the mean and standard deviation of the samples are shown in table 5.3. The average acceptance ratio of the candidate samples  $\theta'$  is 44%, which indicates the method works well

(Roberts et al., 1997). The stability of the sample mean and standard deviation of each parameter is examined in figure 5.7. The mean and standard deviation of the samples converge after the first 1000 samples are added. The most probable values of the parameters from maximization of the posterior pdf are also shown in figure 5.7. Note that the means of the marginal pdf's and the most probable values of the joint posterior pdf need not agree if these pdf's are skewed.

The distribution of sample values for parameters  $\theta$  and the resulting histogram of probability that a station is near-source calculated by the generated set of parameters are shown in figure 5.8. The distribution of parameter samples agrees well with the Gaussian distribution defined by the optimal parameters and standard deviations given by the asymptotic approximation. The standard deviations of  $c_1$  and  $c_2$  are similar to each other and the distribution is peaked close to the mean of the samples. The distribution of samples for the decision boundary constant  $d$  has a standard deviation almost three times as large as that of  $c_1$  and  $c_2$ . However, in terms of coefficient of variation, the uncertainty in  $d$  is smaller than that of other parameters (11.7% compared with 14.9% and 15.3% for  $c_1$  and  $c_2$ , respectively).

Figure 5.9 shows the correlation of samples of model parameters generated from the simulation. This is the result of the model class with all parameters corresponding to the eight ground motion parameters, not the result of the optimal model class. The figure shows that the parameter  $d$  is not correlated significantly with any other parameter. The combinations of parameters which have significant interaction are horizontal and vertical jerk ( $c_1$  and  $c_2$ ), horizontal and vertical acceleration ( $c_3$  and  $c_4$ ), and horizontal and vertical displacement ( $c_7$  and  $c_8$ ). Parameters with the same component and similar frequency range (e.g., jerk and acceleration ( $c_1$  and  $c_3$ , and  $c_2$  and  $c_4$ ), acceleration and velocity ( $c_3$  and  $c_5$ , and  $c_4$  and  $c_6$ ), velocity and displacement ( $c_5$  and  $c_7$ , and  $c_6$  and  $c_8$ )) are also strongly correlated. This result agrees with our intuition; horizontal and vertical components of the same quantity are correlated, and records with similar frequency ranges have similar attenuation relationships and so are correlated.

Figure 5.6: Samples generated by the Metropolis algorithm plotted in the parameter space. The x-axis denotes the sample number. The vertical dotted lines indicate the end of the burn-in period (100 samples).

Figure 5.7: Mean and standard deviation of samples plotted against the number of samples included (excluding first 100 samples). The solid line is the sample mean, and the dashed lines represent the mean plus and minus one standard deviation. The small circle is the most probable values of the model parameters estimated from optimization.

Figure 5.8: Distribution of samples for 3 parameters generated by the Metropolis algorithm. The Gaussian distributions obtained from the asymptotic approximation are added in the figure, and fit the histogram well.

### 5.2.3 Comparison between traditional LDA and Bayesian approach

Parameters for the linear discriminant function  $f(X_i|\theta) = \sum_{k=1}^m c_k x_{ik} - d$  are estimated by traditional LDA and by the Bayesian approach with two different techniques to characterize the posterior pdf. The results are shown in table 5.3. The parameters for LDA are scaled such that the norm of the vector  $c = [c_1, c_2]$  is equal to the norm of the vector from the asymptotic approximation. Note that the discriminant function  $f(X_i|\theta)$  is a linear function, so for the traditional LDA, multiplying all  $c_k$  and  $d$  by an arbitrary positive constant does not change the result of classification. However, this is not true for the Bayesian approach, where the modulus of  $f(X_i|\theta)$  affects the probability that a station is near-source.

The estimated parameters are close for the three methods. The coefficients from LDA are within one standard deviation of those from both Bayesian methods, except that  $c_1$  from LDA is slightly over one standard deviation from the corresponding mean and most probable values from the Bayesian methods.

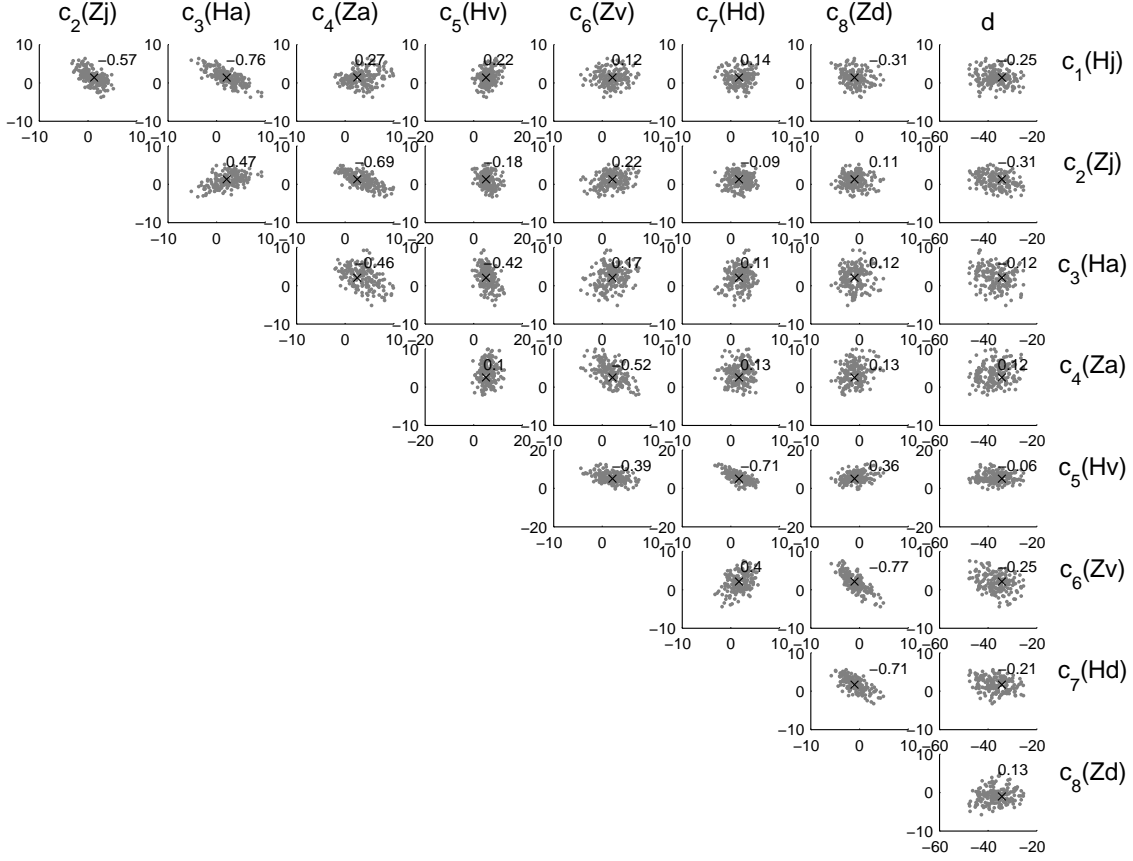

Figure 5.9: Correlation plot of posterior samples of the model parameters generated by the Metropolis algorithm. The most probable values of the parameters are shown as “x”. The numbers in the figure are the correlation coefficient of parameters.

For the asymptotic approximation and Metropolis algorithm, the estimates and standard deviations for the posterior parameter distribution are very close. If the posterior is a skewed pdf, the mean is not necessarily equal to the most probable value (e.g., consider lognormal distribution), as mentioned before. However, figure 5.8 suggests that the posterior pdf is almost symmetric, and the means of the samples and the most probable values should show very good agreement. In this case, the Gaussian distribution is a good approximation for the posterior pdf of the parameters.

By using the discriminant functions defined by the values of the parameters in table 5.3, we performed a classification analysis using the whole dataset. The classification performance for the discriminant function from LDA and two Bayesian

approaches are shown in table 5.5. The results for LDA show 100% of near-source data and 86% of far-source data are classified correctly, and the result of Bayesian approach shows 78% of near-source data and 98% of far-source data are classified correctly. This discriminant function is the function which has the smallest prediction error. To obtain this function, the misclassification of near-source data and that of far-source data are considered to be of equal importance. Generally speaking, the misclassifications of near-source data is more critical than that of far-source data, and we may want to decrease the misclassification rate of near-source data. This misclassification rate can be easily controlled by changing the decision boundary constant  $d$ . We also can control this by shifting the near-source versus far-source boundary in the Bayesian approach to correspond to some other probability than the 1/2 used in this classification analysis.

Table 5.5: The confusion matrix for near-source versus far-source classification by the discriminant function obtained from LDA, Bayesian approach with asymptotic approximation, and Bayesian approach with Metropolis algorithm.

Dataset	NS/FS	Near-source	Far-source
LDA	NS	100 (100%)	0 (0%)
	FS	82 (14%)	513 (86%)
Bayesian-Assym.	NS	78 (78%)	22 (22%)
	FS	12 (2%)	583 (98%)
Bayesian-MA	NS	78 (78%)	22 (22%)
	FS	12 (2%)	583 (98%)

We performed the leave-one-out cross-validation to compare the misclassification rate between LDA and the Bayesian method with asymptotic approximation. The idea of this method is to predict the probability of a station from the discriminant function constructed from the dataset from which that station is excluded. This process is repeated for all 695 data and the accuracy of prediction is computed. The percentage of misclassified data is shown in table 5.6. It shows the prediction error of the Bayesian approach is much smaller than that of LDA. In other words, the Bayesian approach is able to construct a more robust discriminant function. Therefore, we use the discriminant function obtained from the Bayesian method with asymptotic

approximation for further analysis.

Table 5.6: Results of leave-one-out cross-validation for LDA and Bayesian approach.

Method	Prediction Error
LDA	82 / 695 (12%)
Bayesian approach	36 / 695 (5%)

## 5.3 Bayesian model class selection

### 5.3.1 Method

Bayesian model class selection determines which combination of the eight ground motion parameters gives the best classification for the near-source and far-source. The essential idea is to find the most probable model class based on data  $D_n$  within a set of candidate model classes  $M_j$ ,  $j = 1, \dots, J$  (Beck and Yuen, 2004). Applying Bayes' theorem, the probability of model class  $M_j$  can be expressed as follows:

$$P(M_j|D_n, M) = \frac{\overset{\text{evidence}}{p(D_n|M_j)}\overset{\text{prior}}{P(M_j|M)}}{\underset{\text{normalizing constant}}{p(D_n|M)}}, \quad (5.20)$$

where

$M = \{M_1, M_2, \dots, M_J\}$  : a set of candidate model classes,

$J$  = number of the model classes.

The left-hand side of equation 5.20 is the probability of a particular model class  $M_j$  given the dataset and a set of candidate model classes. On the right-hand side,  $p(D_n|M_j)$  is the evidence for each model class,  $P(M_j|M)$  is the prior over the candidate model classes evaluated for  $M_j$ , and  $p(D_n|M)$  is a normalizing constant given

by:

$$p(D_n|M) = \sum_{j=1}^J p(D_n|M_j)P(M_j|M). \quad (5.21)$$

Assuming a uniform prior for the model class,  $P(M_j|M)$  in the numerator and denominator of equation 5.20 cancel. By the total probability theorem, the evidence for  $M_j$  provided by the dataset  $D_n$  is given as:

$$p(D_n|M_j) = \int_{\theta_j} p(D_n|\theta_j, M_j)p(\theta_j|M_j)d\theta_j. \quad (5.22)$$

This is simply the integral of the likelihood of the data for a vector of parameters weighted by its prior probability integrated over the whole parameter set for  $\theta_j$  for model class  $M_j$ .

An asymptotic approximation for large sample sizes  $n$  can be used to compute the evidence of the model (Papadimitriou et al., 1997):

$$p(D_n|M_j) \approx \frac{2\pi^{N_j/2}p(\hat{\theta}_j|M_j)}{\sqrt{|H_j(\hat{\theta}_j)|}} \times \underset{\text{Ockham factor}}{p(D_n|\hat{\theta}_j, M_j)}, \quad (5.23)$$

where

$$H_j(\theta_j) = -\nabla\nabla \log[p(D_n|\theta_j, M_j)p(\theta_j|M_j)],$$

$\hat{\theta}_j$  = optimal parameter vector (most probable value) for model class  $M_j$ ,

$N_j$  = number of parameters for model class  $M_j$ .

Here,  $H_j(\theta_j)$  is given by equation 5.16 for the choice of parameters  $\theta_j$  corresponding to model class  $M_j$ .  $p(\hat{\theta}_j|M_j)$  is the prior defined in equation 5.10 and  $p(D_n|\hat{\theta}_j, M_j)$  is the likelihood function defined in equation 5.13, evaluated at the optimal parameter vector for model class  $M_j$ . For the model class selection, the effect of the number of the parameters,  $N_j$ , in the Gaussian prior is significant if the standard deviation,  $\sigma$ ,

is large. However, the prior we chose is not affected by this issue (we demonstrate this later).

### 5.3.2 Results of Bayesian model class selection

We used Bayesian Model Class Selection to find the best combination of the eight ground motion parameters with the same dataset as the previous classification problem. First, we impose the condition that both horizontal and vertical components be included in the model for any selected ground motion quantity. Under this condition, there are four groups of ground motion parameters (peak jerk, acceleration, velocity, and filtered displacement) giving fifteen possible combinations. These fifteen candidate model classes are shown in table 5.7.

Table 5.7: Results for Bayesian model class selection when fifteen combinations of the ground motion parameters are examined under the condition that the horizontal and vertical components are used together. The most probable value of the decision boundary parameter corresponding to each ground-motion parameter is given first for each model class. The values for the Ockham factor (Ock.), likelihood (like.), and evidence (evi.) of each model class are log scaled. The last column is the posterior probability that measures how plausible the model class is. It is scaled such that the total probability of the fifteen model classes is 100%.

The results in table 5.7 indicate that the combination of acceleration and veloc-

ity is the model with highest probability, although the jerk and velocity combination also has significant probability. The log of prior ( $p(\hat{\theta}_j|M_j)$ ) is simply a function of  $N_j$  and becomes smaller as the number of parameters increases. The factor  $p(\hat{\theta}_j|M_j)(2\pi^{N_j/2})/\sqrt{|H_j(\hat{\theta}_j)|}$  in equation 5.23 is called the Ockham factor by Gull (Gull, 1988; Beck and Yuen, 2004). It penalizes a more complicated model and so makes a simpler model preferable. The Ockham factor is also shown in table 5.7. Although the coefficient  $2\pi^{N_j/2}$  and  $\sqrt{|H_j(\hat{\theta}_j)|}$  are included in the Ockham factor, the effect of prior  $p(\hat{\theta}_j|M_j)$  is dominant.

The log of the likelihood function  $p(D_n|\hat{\theta}_j, M_j)$  becomes larger as the number of the parameters in the model class increases because a more complicated model class will fit the data better than a less complicated one. However, the Bayesian model class selection automatically accounts for the trade-off between the complexity of the model (e.g., number of parameters) and the fit of the data to find a well-balanced model (Beck and Yuen, 2004).

To examine the possible model classes further, the constraint that horizontal and vertical components be used together is removed. We test all 255 model classes created from the combinations of 8 parameters. The results for the best five model classes are shown in table 5.8. The sum of the posterior probability of the five model classes is 95% out of all 255 model classes.

Table 5.8: The best five model classes in the Bayesian model class selection when 255 combinations of the ground motion parameters are examined. The columns are in the same format as in table 5.7.

model	Hj	Zj	Ha	Za	Hv	Zv	Hd	Zd	d	Ock.	Like.	Evi.	P(%)
1	-	-	-	6.05	7.89	-	-	-	27.1	-15	-81	-96	80.8
2	1.91	-	-	4.41	8.31	-	-	-	31.9	-20	-79	-99	6.6
3	-	-	1.86	4.88	7.86	-	-	-	29.2	-20	-80	-100	2.9
4	-	1.59	-	4.31	8.02	-	-	-	29.7	-20	-80	-100	2.5
5	-	4.43	-	-	8.52	-	-	-	32.2	-16	-84	-100	1.9

Model class 1, which has the coefficients of the vertical acceleration and horizontal velocity, is the most probable model within the set of 255 model classes. The

discriminant function for the most probable model in model class 1 is:

$$f(X_i|\theta) = 6.046 \log_{10} Za + 7.885 \log_{10} Hv - 27.091, \quad (5.24)$$

where

$$P(Y_i = 1|X_i, \theta) = \frac{1}{1 + e^{-f(X_i|\theta)}}, \quad (5.25)$$

is the probability that station  $i$  is near-source. This result indicates that the amplitude of high-frequency components is effective in classifying near-source and far-source stations. Note that the probability that the station is near-source is higher, if  $f$  is larger.

### 5.3.3 Effect of the choice of prior

In this section, we examine the choice of prior for the parameters in the model class selection. As we stated, for the Gaussian prior distribution, the effect of the number of parameters,  $N_j$ , is significant if the prior standard deviation,  $\sigma$ , is large (Lindley, 1957; Muto, 2006). We demonstrate this feature by performing model class selection with a Gaussian prior with different values of  $\sigma$  and a uniform prior with different widths of boundary  $b$ . The posterior probabilities of the model class selections are shown in table 5.9.

In the table, we can see the effect of the prior standard deviation in the Gaussian prior. As we increase  $\sigma$ , it tends to bias the posterior probability toward simpler models (i.e., models with fewer parameters). For example, the probability of model *jav* slightly decreases as  $\sigma$  increases. The small probability of model *juv* with Gaussian prior ( $\sigma=10$ ) is caused by the narrow prior range. If  $\sigma$  is too small, it restrict the range of parameters as shown in table 5.10. Therefore, the choice of  $\sigma=100$  is reasonably wide enough to find the most probable parameters, so we chose it in the Bayesian approach.

For the uniform prior, we are able to choose the small width of the boundary

Table 5.9: The posterior probability of the model class selection with different types of prior distribution for parameters.  $\sigma$  is the standard deviation for the Gaussian distribution and  $|b|$  is the width of the boundary for the uniform distribution.

Model	Gaussian prior			Uniform prior	
	$\sigma=10$	$\sigma=100$	$\sigma=1000$	$ b  < 20$	$ b  < 100$
j	0.0	0.0	0.0	0.0	0.0
a	0.0	0.0	0.0	0.0	0.0
v	0.0	0.0	0.0	0.0	0.0
d	0.0	0.0	0.0	0.0	0.0
ja	0.0	0.0	0.0	0.0	0.0
jv	7.2	32.4	33.0	31.5	32.9
jd	0.0	0.0	0.0	0.0	0.0
av	78.9	62.1	61.7	59.0	61.6
ad	7.3	5.3	5.3	5.0	5.3
vd	0.0	0.0	0.0	0.0	0.0
jav	3.3	0.1	0.0	3.0	0.1
jad	0.1	0.0	0.0	0.0	0.0
jvd	0.1	0.0	0.0	0.3	0.0
avd	3.0	0.0	0.0	1.1	0.0
javd	0.1	0.0	0.0	0.0	0.0

Table 5.10: The estimated parameters from Bayesian approach with different types of prior distribution for parameters.

Prior	$c_1$ (Za)	$c_2$ (Hv)	$d$
Gaussian( $\sigma=10$ )	5.522	7.147	24.686
Gaussian( $\sigma=100$ )	6.046	7.885	27.091
Gaussian( $\sigma=1000$ )	6.053	7.895	27.122
Uniform Cases	6.053	7.895	27.122

since the uniform prior does not affect the most probable parameter if the parameter is inside the boundary. We show the results of model class selection of uniform prior with  $|b| < 20$  and  $|b| < 100$  ( $|b| < 10$  is not wide enough to find the most probable parameters). They are almost the same, but the probability of model jav decreases a little as  $|b|$  increases.

We conclude that in this problem, the effect of the choice of prior is small. In other words, the likelihood in equation 5.23 is very peaked and the prior pdf does not

significantly affect the probability of the model.

## 5.4 Results and discussion

We apply the optimal discriminant function from Bayesian approach (in equations 5.24 and 5.25) to all the stations in the dataset. Figure 5.10 shows the classification results. The distribution of stations with a high probability of being in the near-source is consistent with the fault geometry. As mentioned before, the fault models that are used here are those from the source inversion, and they are not necessarily the best indicator of near-source and far-source stations.

To examine the application for real-time analysis, the optimal discriminant function in equations 5.24 and 5.25 is applied to the Chi-Chi earthquake strong motion records. We generated snapshots of the probability that a station is near-source from 10 to 40 seconds after the beginning of rupture. Peak ground motions used for this classification analysis are computed from the observed data every 10 seconds for each station and evaluated in the discriminant function. The results are shown in figure 5.11. A darker mark at a station in figure 5.11 indicates that the station is more likely to be near-source, and a lighter mark indicates that the station is more likely to be far-source.

Ten seconds after the rupture initiation, the map shows that stations with high probability of being in the near-source are located near the epicenter, and it indicates that the rupture area is propagating concentrically. At 20 seconds, the probability of being in the near-source at thirteen stations is computed to be greater than 50%, but the concentric station distribution makes it difficult to identify any directivity of rupture propagation. The average slip velocity is 2 km/s (Ji et al., 2003), and the rupture front propagates 40 km from the hypocenter at this point. We can see the North – South character of the rupture direction clearly after 30 seconds of rupture. At 40 seconds, the distribution of stations with high near-source probability agrees with the fault surface projection, and stations at the near-source and far-source boundary have around 50% probability. Even though the fault geometries used for

the wave inversion are not necessarily the actual extent of the fault, to a first-order approximation, the classification results are in good agreement with them.

## 5.5 Summary

We presented a methodology to classify seismic records into near-source or far-source records as a prelude to estimating fault dimension in an earthquake early warning system. Ground motion records from some past earthquakes are analyzed to find a linear function that best discriminates near-source and far-source records. Peak values of jerk, acceleration, velocity, and displacement are used in a traditional LDA and in a Bayesian approach to find the linear combination of peak values which provides the best performance to classify near-source and far-source records. All methods gave similar discriminant functions. We also analyzed which combination of ground motion features had the best performance for classification using Bayesian model class selection, and the best discriminant function is:

$$f(X_i|\theta) = 6.046 \log_{10} Za + 7.885 \log_{10} Hv - 27.091, \quad (5.26)$$

$$P(Y_i = 1|X_i, \theta) = \frac{1}{1 + e^{-f(X_i|\theta)}}, \quad (5.27)$$

where  $Za$  and  $Hv$  denote the peak values of the vertical acceleration and horizontal velocity, respectively, and  $P(Y_i = 1|X_i, \theta)$  is the probability that a station is near-source. This function indicates that the amplitude of high-frequency components is effective in classifying near-source and far-source stations.

The probability that a station is near-source obtained using this optimal discriminant function for all the earthquakes shows the extent of the near-source area quite well, suggesting that the approach provides a good indicator of near-source and far-source stations for real-time analyses. Note that this function is constructed by the training dataset with magnitude greater than 6.0, so it only works for large earth-

## Chapter 6

# Estimating the Slip on the Fault from Low-Frequency Ground Motion

We developed a methodology to recognize the fault rupture geometry by incorporating the characteristics that high-frequency ground motions have stronger correlation with the fault rupture distance. However, it is difficult to predict the slip on the fault from high-frequency ground motions, since the near-source high-frequency ground motions saturate as a function of magnitude for large earthquakes. Therefore, we use low-frequency ground motions to determine the slip on the fault.

Low-frequency ground motion is important in a sense that it allows for the prediction of long-period seismic waves and the present value of slip on a rupture allows for a probabilistic prediction of additional rupture in the near future. Additionally, low-frequency ground motion increases exponentially as a function of magnitude, and is important to estimate seismic damage.

In this chapter, we propose a methodology to determine the slip on the fault that is compatible with both the observed low-frequency motions and also with the rupture geometry determined from high-frequency motions. We also create a methodology to predict the total length of the rupture propagation conditioned on the current slip size.

Currently, the displacement data is obtained from the double integration of strong motion records, and it is difficult to remove the linear trend from inertial seismometers

in real-time analysis (Clinton, 2004). To determine the fault slip in real time, the future incorporation of real-time high-sample-rate GPS into early warning systems may be quite important.

Our method to recognize the slip on the fault in real time also works for tsunami warning because tsunami energy can be estimated by the slip on the fault. It is more effective for tsunami warning since the warning time is generally much larger than earthquake early warning.

## 6.1 Data

The strong motion data for Chi-Chi earthquake (September 20, 1999) are used for this analysis. This is the same dataset as the one in the near-source versus far-source classification analysis, and the data source is explained in section 5.1.1.

To obtain the real displacement data from strong motion records, we applied the following procedure. First, the DC offset of the accelerograms is corrected by subtracting the mean of the pre-event portion. The corrected accelerograms are integrated once to obtain the velocity records. Some velocity records have a linear trend due to either tilting, the response of the transducer to strong shaking, or problems in the analog-to-digital converter. Therefore, the baseline correction scheme explained in section 5.2.2 is applied to obtain appropriate velocity records. After time-domain integration of this corrected velocity, the approximated real displacements will be obtained. If the post-events displacement is not constant, the coefficients  $a_1$  and  $a_2$  in equation 5.1 are manually determined so that the post-events velocity is zero. In this way, approximated real displacement records are obtained.

This baseline correction scheme does not necessarily produce the real displacement records, since the scheme assumes the baseline shift of the acceleration occurs only once. Therefore, we compare the static displacement measured after the event with the GPS displacement data. The location of GPS stations are not the same as that of strong motion stations, but the displacement of the GPS station which is the nearest neighbor of the strong motion station is compared with the displacements

(a) Static displacements from GPS records. GPS stations are shown by open triangles.

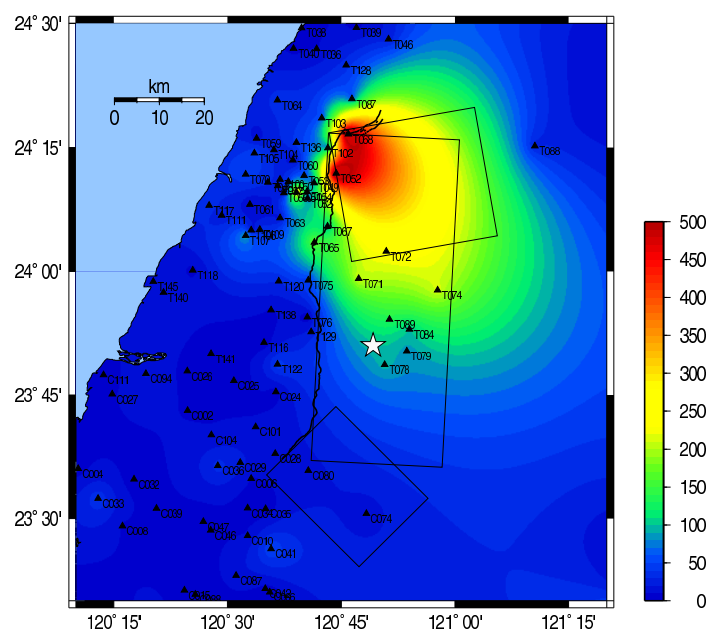

(b) Static displacements from strong motion records. Strong motion stations are shown by solid triangles.

Figure 6.1: Distribution of the static displacements for the Chi-Chi earthquake (EW component). The star symbol denotes the epicenter of the earthquake. The rectangular boxes display the map projection of the fault geometry proposed by Ji et al. (2003). The distribution of static displacements computed from strong motion records agrees well with the one from GPS displacements.

obtained from double integration of strong motion records. Figures 6.1 – 6.3 show the comparison between the GPS displacement and static displacement computed from the strong motion records by applying the baseline correction scheme. The map for GPS displacement shows higher values on the hanging wall since there are more GPS stations than strong motion stations on the hanging wall. However, overall, the static displacement distribution computed from strong motion records agrees well with the GPS displacement and this suggests that our baseline correction scheme is reasonable.

## 6.2 Estimating the slip on the fault from low-frequency ground motion

### 6.2.1 Constructing a slip function as a function of fault distance

Aagaard et al. (2004) simulated near-source ground motions for five fault geometries with different combinations of fault dip and rake angles. Four of the simulated near-source peak ground displacements as a function of distance from the fault for scenarios with the shallow hypocenter are shown in figure 6.4. The average slip and fault area for scenarios across the different fault dip angles are constant. In figure 6.4, the value of maximum ground displacement normalized by the unit average slip is shown on the vertical axis. The peak ground displacement per unit slip is not significantly different for different fault scenarios, except the displacement for the strike-slip fault scenario (dip angle =  $90^\circ$ ) is symmetric along the fault line and the displacement for the thrust fault scenario (dip angle =  $45^\circ$ ,  $60^\circ$ , and  $75^\circ$ ) is asymmetric and records larger amplitude on the hanging wall.

We fit an analytical function to this simulated ground displacement ( $x$ ) as a function of fault distance ( $r$ ). Using a bell-shape function  $x(r) = x(0)/\sqrt{1 + (\alpha|r|)^\beta}$ , we find  $\alpha$  and  $\beta$  by minimizing the least-square errors between the simulated near-field

Figure 6.4: A displacement per unit slip as a function of fault distance obtained from ground motion simulations (Aagaard et al., 2004). An approximated curve for the strike-slip fault scenario (dip angle =  $90^\circ$ ) is added in the thick line.

ground displacements and the bell-shape function. Assuming the ground displacement is proportional to the slip on the fault, the analytical function which approximates the simulated ground displacement is:

$$x(r) = \frac{0.7}{\sqrt{1 + (0.125|r|)^{1.55}}} \times slip. \quad (6.1)$$

For the proposed real-time analysis method, we back project the recorded displacement data onto the fault line to estimate the size of the slip on the fault. In the current state-of-the-art seismic network, the seismometer directly measuring the ground displacement, such as high-sampling GPS, is not as common as strong motion seismometer. We obtain the ground displacement by the double integration of the strong motion records or the single integration of the records of the broadband

seismometer.

The location of the epicenter and the direction of the fault rupture are assumed to be estimated from the previous technique to recognize a rupture geometry (chapters 4 and 5). We define the fault line as a straight line on the epicenter oriented in the direction of the fault rupture, and the fault distance as the distance between the station and the fault line (see figure 6.5 as an example of calculating the fault distance). From equation 6.1, the slip on the fault line when the displacement ( $x$ ) is recorded at the fault distance ( $r$ ) is estimated by the following equation:

$$slip = \frac{x(r)}{0.7/\sqrt{1 + (0.125|r|)^{1.55}}}. \quad (6.2)$$

### 6.2.2 Estimating the slip on the fault and predicting the additional rupture extent

We estimated the slip on the fault of the Chi-Chi earthquake from the strong motion records and compared with the slip distribution computed it from the seismic waveform inversion (Ji et al., 2003). Figure 6.6 shows the slip distribution of the Chi-Chi earthquake (1999) obtained from the seismic waveform inversion (Ji et al., 2003).

The solid line in figure 6.7 shows the cross section of the slip distribution along AB which is identical to the fault line in figure 6.5. Figure 6.7 also shows the back projection of the observed ground displacement data onto the fault line after 10, 20, and 30 seconds after the origin time. Only the records of the stations where the rupture front arrived are shown in the figure. From the figure, we can see the back projection of the displacement records agrees with the slip distribution obtained from the waveform inversion to a first-order approximation. There is a large discrepancy at the north end of the fault line (40 km north from the epicenter). It shows that the most of the displacement records underestimate the slip on the fault and one station which significantly overestimate the slip on the fault. This is because there are many stations on the foot wall and few stations on the hanging wall of the fault for the Chi-

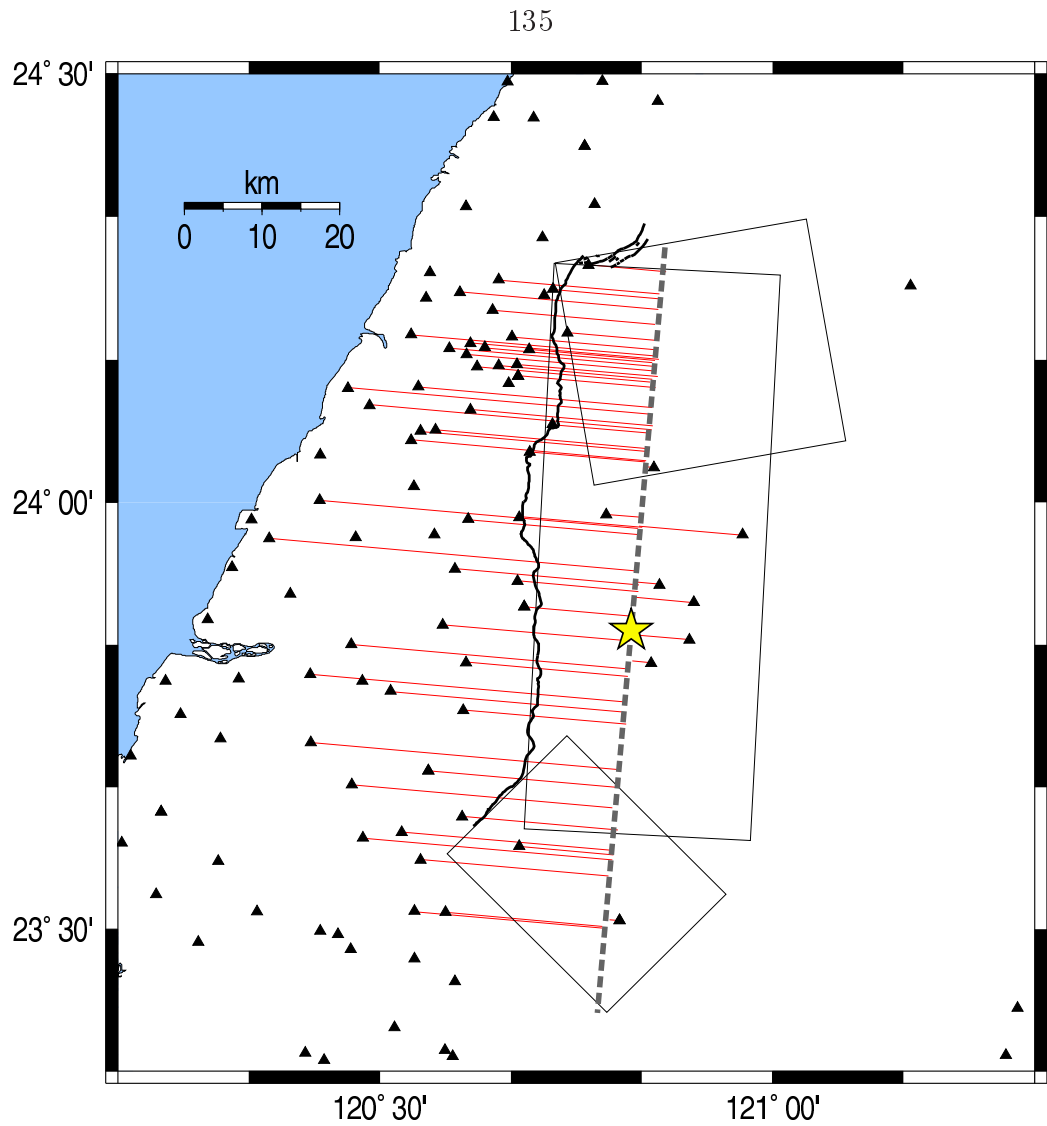

Figure 6.5: A slip on the fault can be obtained by backprojecting the displacement from the strong motion data onto the fault line shown as a thick broken line.

Chi earthquake. Additionally, we use the slip function which fits to the near-source ground motion simulation for strike-slip fault, while the Chi-Chi earthquake source is thrust fault and the slip on the fault is significantly asymmetric along the fault line.

Figure 6.6: Slip distribution for the Chi-Chi earthquake proposed by Ji et al. (2003). The model consists three rectangular planes crossing in three dimension. The cross section along the fault line AB is shown in figure 6.7

### 6.3 Predicting the probability of the additional rupture extent

Given the current slip on the fault, what is the probability that the rupture length exceeds a certain number? To answer this question, we create a methodology to predict the total length of the rupture propagation conditioned on the current slip size. Liu-Zeng et al. (2005) constructed a methodology to generate simple 1-D models of spatially heterogeneous slip. By using this methodology, we compute the probability of the rupture length ( $L$ ) conditioned on the current slip on the fault ( $D$ ) in a statistic way.

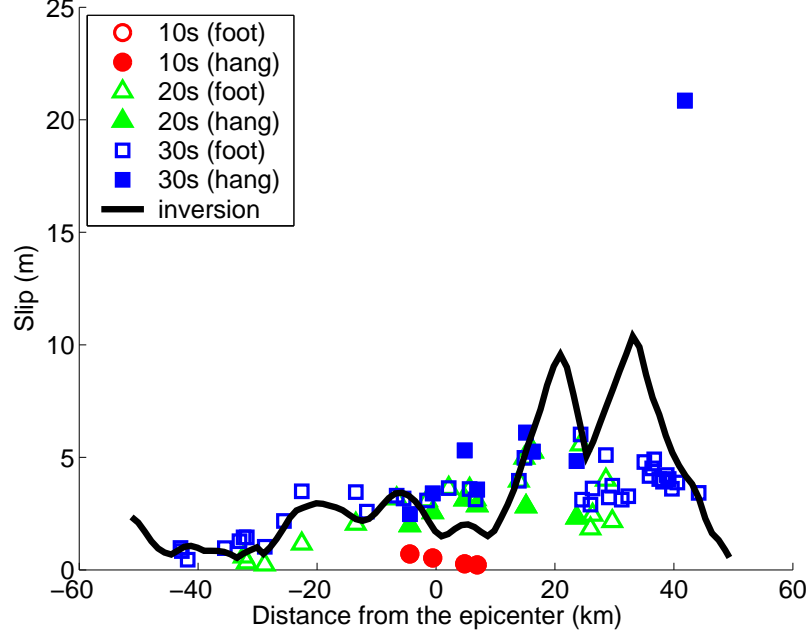

Figure 6.7: Cross section of the slip distribution in figure 6.6. The estimated slip from real-time displacement data are also shown. “Foot” and “hang” indicate stations on the footwall and hanging wall, respectively. The records from the stations on the hanging wall show higher value than that of footwall stations.

### 6.3.1 Generating 1-D slip models

In this section, we briefly discuss the basic procedures of the technique developed by Liu-Zeng et al. (2005).

Let  $w(x)$  be white noise with mean zero and standard deviation one, and then  $W(t)$  be a Fourier transform of  $w(x)$ .

$$W(k) = \mathcal{F}\{w(x)\} \quad (6.3)$$

Applying a low-pass filter  $F(k)$  to  $W(k)$ ,

$$Y(k) = W(k)F(k), \quad (6.4)$$

where  $F(k) = k^{-\alpha}$ ,  $\alpha=1.25 - 1.5$  (Liu-Zeng et al., 2005). If  $\alpha=1$ , applying the low-pass filter is equivalent to a single integration. If  $\alpha=2$ , it is equivalent to a double

Figure 6.8: An example of the 1-D slip models. Top: an original white noise. Bottom: a parent series generated by the low-pass filtering of the white noise.

integration. Taking an inverse transform of  $Y(k)$ , a low-pass filtered white noise is obtained.

$$y(x) = \mathcal{F}^{-1}\{Y(k)\} \quad (6.5)$$

Figure 6.8 shows an example of the white noise  $w(x)$  and low-pass filtered white noise  $y(x)$ . We call this generated series  $y(x)$  the “parent series.” We define the end of an individual rupture when the parent series crosses the zero line, and then take the absolute value of the individual series. In this way, each parent series is split into a set of earthquake slip models of varying length with approximately the same smoothness  $\alpha$ . Taking a modulus of the parent series, the slip  $D$  as a function of position  $x$  is:

$$D(x) = D_0|y(x)|, \quad (6.6)$$

where  $D_0$  is a constant defined from the observation. The distance between adjacent

Figure 6.9: The effect of the low-pass filter with different order  $\alpha$  on the slip models. Larger  $\alpha$  can generate smoother series.

data points  $\Delta x$  is assumed to be  $\Delta x = 10$  m.

### 6.3.2 Characteristics of the 1-D slip models

The order of the low-pass filter ( $\alpha$ ) can control the smoothness or roughness of the slip models. By definition of low-pass filter,  $\alpha$  is the slope of its Fourier spectral amplitude with wave number. Therefore, as  $\alpha$  increases, the applied filter removes more high-frequency components. Figure 6.9 shows generated parent series with three different orders of the low-pass filter. Applying the low-pass filter with smaller  $\alpha$ , the generated series consists of much higher frequency component. If  $\alpha$  of the low-pass filter is large, the generated series becomes smoother. The value of  $\alpha$  controls not only the roughness of the slip model. A model with a rougher slip distribution (smaller  $\alpha$ ) has higher chance to cross the zero line. Therefore, models with smaller  $\alpha$  will generate more short events.

Figure 6.10 shows the relationship of the average slip ( $\bar{D}$ ) and the rupture length ( $L$ ) of each model for three different  $\alpha$ . The regression curves and regression equations

Figure 6.10: Plot for the average slip ( $\bar{D}$ ) and rupture length ( $L$ ) for the slip models with different  $\alpha$ . Regression lines for each  $\alpha$  are added in the figure. The parameter  $\alpha$  controls the slope of the regression lines.

for each case are also added in the figure. The slope of the regression curves varies with different  $\alpha$ , and the slip model with smaller  $\alpha$  shows the steepest slope. This means the rougher slip distributions (smaller  $\alpha$ ) produce longer ruptures for a given average slip. That is because for a given slip, a rupture is more likely to terminate in a short distance.

The parameter  $\alpha$  is determined so that the regression curve for  $\bar{D}$  and  $L$  agrees with the observation. Figure 6.11 shows the  $\bar{D}$  and  $L$  relationship of real earthquakes in a log-log plot. The strike-slip events from the dataset by Wells and Coppersmith (1994) and Liu-Zeng et al. (2005) are used in this figure. The trend of the regression line for non-interplate events and interplate events are similar, so the regression line for total dataset ( $\log_{10} \bar{D} = 0.85 \log_{10} L - 1.43$ ) is added in the figure. The slope of the regression curve for  $\bar{D}$  and  $L$  scales with  $\alpha$  (see figure 6.12), so the value of  $\alpha$  which corresponds to the observed slope for  $\log_{10} \bar{D} / \log_{10} L = 0.85$  is 1.33. The intersection of the regression line for  $\bar{D}$  and  $L$  depends on  $\alpha$  and the constant  $D_0$  in equation 6.6,

Figure 6.11: Plot for the average slip ( $\bar{D}$ ) and rupture length ( $L$ ) for the observed earthquake data in Wells and Coppersmith (1994) and Liu-Zeng et al. (2005).

Figure 6.12: Plot for the slope of  $\log \bar{D} / \log L$  and  $\alpha$ . The value of  $\alpha$  that corresponds to the observed slope (0.85) is 1.33.

Figure 6.13: Plot for the average slip ( $\bar{D}$ ) and rupture length ( $L$ ) for the observed data and simulation results from the slip model with  $\alpha = 1.33$ .

and the value of  $D_0$  which agrees with the observation is 0.02. Figure 6.13 shows  $\bar{D}$  and  $L$  generated by the model with  $\alpha=1.33$  and  $D_0=0.02$ . The samples generated from models with these parameters agree with the real observations very well.

Figure 6.14 shows the comparison of the models with different numbers of the parent series ( $n$ ). Even though the models with smaller  $n$  generate more short events, the slope of  $\bar{D}$  and  $L$  does not change so much in the range of  $n = 2^{18}, 2^{19}$  and  $2^{20}$ . We conclude that the number of the parent series is not important to control the roughness of the models.

### 6.3.3 Statistical distribution of the additional rupture length

Using the Liu's method to generate 1-D slip models (Section 6.3.1), the statistical distribution of the rupture length conditioned on current slip on the fault is examined. First, we generated 1000 parent series with length  $2^{20}$ , and 5254 models are obtained from the series. For each model, when the slip exceeds a certain value, the length between the current location and the location where the rupture terminates

Figure 6.14: Plot for the average slip ( $\bar{D}$ ) and rupture length ( $L$ ) for the slip models with different parent series size  $n$ . The slope of  $\bar{D}$  and  $L$  does not change so much in the range of  $n = 2^{18}$ ,  $2^{19}$ , and  $2^{20}$ .

Figure 6.15: 3-D histogram of the additional rupture length ( $L_a$ ) as a function of current slip ( $D$ ).

is computed. We call this length the additional rupture length  $L_a$ , as opposed to the total rupture length of each model  $L$ . The statistical distribution of additional rupture length for different current slip sizes is shown in figure 6.15.

Figure 6.15 shows a histogram of additional rupture length conditioned on current slip on the fault. Here, the bin size of the histogram is 10 km. The figure shows that the rupture with small current slip has high probability that the additional rupture length is small and more likely to terminate in the near future. The 2-D plot of figure 6.15 is shown in figure 6.16 for later comparison.

Next, we try to describe the probability density for these samples by an analytical function. Using a Gaussian function as a kernel function (Silverman, 1986), the probability density can be estimated as a summation of Gaussian distributions. Given the samples  $C = [c_1, c_2, \dots, c_n]$ , the probability density of the samples can be estimated by:

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}} \frac{1}{n} \sum_{i=1}^n \exp\left(-\frac{(x - c_i)^2}{2\sigma^2}\right), \quad (6.7)$$

where  $n$  is the number of the samples and  $\sigma$  is a standard deviation of the kernel function. The  $\sigma$  controls the smoothness of the estimated density and we found the kernel function with constant  $\sigma = 10$  estimates reasonably smooth distribution to approximate the original histogram. The estimated probability density is shown in figure 6.17, which is a very good approximation of the histogram in figure 6.16 .

The probability density estimated from the Gaussian kernel function is very accurate, but expensive to compute, since the function (equation 6.7) includes  $n$  exponential terms. Therefore, we try to approximate the probability density by using a single lognormal distribution.

Lognormal distribution is a probability distribution of any random variable whose logarithm is Normally distributed. The lognormal distribution has the probability

density function (pdf):

$$p(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-(\ln x - \mu)^2 / 2\sigma^2}. \quad (6.8)$$

The distribution is defined by two parameters: mean  $\mu$  and standard deviation  $\sigma$  of the variable's logarithm. These two parameters are computed by fitting mode of the distribution (the value of the term that occurs the most often) and the probability density at the mode (peak value of the probability density). The mode of the lognormal distribution is  $e^{\mu - \sigma^2}$  and the probability density at the mode is  $\frac{1}{\sigma\sqrt{2\pi}} e^{-\mu + \sigma^2/2}$ . The computed  $\mu$  and  $\sigma$  for each slip size  $D$  are shown in figure 6.18. Since the relationship between  $\mu$  and  $D$  seems logarithmic, a logarithmic trendline is added in the figure. The regression function is  $\mu(D) = 1.16 \ln(D) + 4.94$ . On the other hand, the parameter  $\sigma$  does not show any dependence with  $D$ . Therefore, we select a constant  $\sigma = 1.6$ .

The lognormal distribution with parameters which are best fit to the probability density is shown in figure 6.19, which is a good approximation of the probability density shown in figure 6.17. The lognormal distribution with parameters  $\mu(D) = 1.16 \ln(D) + 4.94$  and  $\sigma = 1.6$  is also shown in figure 6.20. The difference between figures 6.19 and 6.20 are very minor, so the equations to compute the  $\mu$  and  $\sigma$  are reasonable and valid for the general case.

Figures 6.21 - 6.24 are enlarged graphs of figures 6.16 - 6.20. In those figures, we can see the slope of the approximated lognormal distribution around origin is much higher than that of kernel probability density. They also decay slower than that of probability density after the peak. However, it is important to express this kernel probability density with simpler expression for convenience, and the approximated lognormal distribution is close enough to express the kernel probability density.

From the probability density of the additional rupture length, we also compute the probability that the current rupture propagates more beyond a threshold value  $L_{thre}$  conditioned on the current slip size  $D$ . The probabilities for different  $L_{thre}$  are shown in figure 6.25. The figure shows for larger  $D$ , there is higher probability

that the additional rupture length exceeds  $L_{thre}$ . Besides, the probability increases significantly for the  $D$  greater than 0.2 m. Therefore, if the slip size is less than 0.2 m at the beginning of the rupture, it is difficult to tell how far the rupture can propagate. Once the slip exceeds 0.4 m, there is higher probability that the rupture extends to a large event.

In summary, the probability density obtained from the simulations with 1-D slip models is expressed by:

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}} \frac{1}{n} \sum_{i=1}^n \exp\left(-\frac{(x - c_i)^2}{2\sigma^2}\right), \quad (6.9)$$

where

$n$  = number of the samples,

$c_i, i = 1, \dots, n$  = samples,

$\sigma$  = a standard deviation of kernel function (= 10).

And the probability density function for the approximated lognormal distribution is:

$$p(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-(\ln x - \mu)^2 / 2\sigma^2}, \quad (6.10)$$

where  $\mu(D) = 1.16 \ln(D) + 4.94$  and  $\sigma = 1.6$ .

## 6.4 Summary

In this chapter, we propose a methodology to determine the slip on the fault that and predict the total length of the rupture propagation conditioned on the current slip.

In order to characterize a slip on the fault in real time, we construct an analytical function to estimate slip on the fault from observations of displacement away from the fault by using the result of a ground motion simulation (Aagaard et al., 2004). In real-time analysis, we back project the recorded displacement data onto the fault line scaled by the analytical function to estimate the size of the slip on the fault. The fault slip makes it possible to predict long-period seismic waves, which is important to estimate seismic damage.

This current size of the slip on the fault is used for a probabilistic prediction of additional rupture in the near future. We characterize the distribution of additional rupture length conditioned on the current slip on the fault for the ongoing rupture from the simulation with a 1-D slip model. The probability density of additional rupture length ( $L_a$ ) can be approximated by a lognormal distribution conditioned on the current slip size ( $D$ ).

$$p(L_a|D) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-(\ln L_a - \mu(D))^2 / 2\sigma^2}, \quad (6.11)$$

where  $\mu(D) = 1.16 \ln(D) + 4.94$  and  $\sigma = 1.6$ .

The pdf shows the expectation of additional rupture length is longer as the current slip size is larger. This means a rupture with large current slip is more likely to continue propagating, and a rupture with small current slip tends to terminate shortly. However, the observation is not always the case: for example, rupture of Chi-Chi earthquake in figure 6.7 terminates right after the largest slip occurs at the north end of the fault. Since the mechanism of the rupture propagation is very complicated, it is difficult to predict the end of a rupture. The model proposed here is crude and may not agree with these observation completely, but the technique to generate pdf of additional rupture length from a slip model can apply to other slip models.

# Chapter 7

## Conclusions

Recently, according to advances in data analysis and an increased public perception of seismic hazards, the topic of early warning has attracted more research attention from seismologists and engineers. Earthquake early warning systems collect seismic data from an occurring event, analyze them quickly, and provide estimates for location and magnitude of the event.

Cua and Heaton developed the Virtual Seismologist (VS) method (Cua, 2005; Cua and Heaton, 2006). It is a Bayesian approach to seismic early warning designed for modern seismic networks, and proposed for small to moderate earthquakes with ruptures that can be approximately modeled as a point source. The VS algorithm uses an envelope attenuation relationship and the predominant frequency content from the first few seconds after the P-wave arrival. The advantage of the VS method is its capacity to assimilate different types of information that may be useful to find quick and reliable estimates of magnitude and location (Cua, 2005).

In order to construct an early warning system for large earthquakes, we characterize the rupture extent and the slip on the fault in real time and predict ground motions at a given site based on the current rupture configuration. Our strategy for large earthquakes is as follows:

- Characterize the present rupture extent from high-frequency ground motions.
- Characterize the present slip on the fault from low-frequency ground motions.
- Predict the final rupture extent from the on-going rupture.

- Estimate the ground motion at a given site based on the present rupture geometry.

The ground motions at a site could be different for different earthquakes of the same magnitude at the same distance, because of differences in source mechanisms, path effect, or site conditions. One of the most commonly used ground motion parameters is peak ground accelerations (PGA), and Campbell (1981) found this uncertainty of peak ground acceleration can be modeled using a lognormal distribution. In other words, the distribution of the amplitude of ground motions with constant magnitude and distance follows a lognormal distribution.

The statistical observations of high-frequency and low-frequency ground motions for large earthquakes show that the near-source high-frequency ground motion saturates as a function of magnitude for large earthquakes, and weakly depends on the magnitude. On the other hand, the low frequency ground motion has strong correlation with the magnitude of an earthquake.

### **1) Characterize the present rupture extent from high-frequency ground motions**

We propose a new model to simulate high-frequency motions from earthquakes with large fault dimension: the envelope of high-frequency ground motion from a large earthquake can be expressed as a root-mean-squared combination of envelope functions from smaller earthquakes. We parameterize the fault geometry with an epicenter, a fault strike, and two along-strike rupture lengths, and find these parameters by minimizing residual sum of squares of errors between simulation and observed ground motion envelopes.

To provide the information on the spatial extent of rupture geometry, we present a methodology to estimate the fault dimension of an earthquake in real time by classifying seismic records into near-source or far-source records. We analyze peak ground motions and find the function that best classifies near-source and far-source records based on these parameters by Bayesian model class selection. This discriminant func-

tion is useful to estimate the fault rupture dimension in real time, especially for large earthquakes.

## **2) Characterize the present slip on the fault from low-frequency ground motions.**

In order to characterize a slip on the fault in real time, we construct an analytical function to estimate slip on the fault from observations of displacements away from the fault by using the result of a ground motion simulation (Aagaard et al., 2004). In real-time analysis, we back project the recorded displacement data onto the fault line scaled by the analytical function to estimate the size of the slip on the fault. The fault slip makes it possible to predict long-period seismic waves, which is important to estimate seismic damage.

## **3) Predict the final rupture extent from the on-going rupture**

This current size of the slip on the fault is used for a probabilistic prediction of additional rupture in the near future. We characterize the distribution of additional rupture length as a conditioned on the current slip on the fault for the ongoing rupture from the simulation with a 1-D slip model. The probability density of additional rupture length ( $L_a$ ) can be approximated by a lognormal distribution conditioned on the current slip size ( $D$ ):

$$p(L_a|D) = \frac{1}{L\sigma\sqrt{2\pi}} e^{-(\ln L_a - \mu(D))^2 / 2\sigma^2}, \quad (7.1)$$

where  $\mu(D) = 1.16 \ln(D) + 4.94$  and  $\sigma = 1.6$ .

## **4) Estimate the ground motion at a given site based on the present rupture geometry**

In the current earthquake early warning system, the ground motion at a given site can be estimated by the velocity attenuation relationship as a function of magnitude and epicentral distance, and multiplying site amplification factors. There are imple-

mentation issues on this ground motion estimate, since the ground motion models for large earthquakes depends on rupture dimension and slip size, too. We found out that the high-frequency ground motion at a site can be expressed as a root-mean-squared combination of envelope functions from smaller earthquakes. However, this model does not work for velocity and displacement estimates since it relies on the random phase assumption of high frequency ground motions. Constructing ground motion models for low-frequency ground motions by considering the fault distance and slip size on the fault still remains as future work.

## Appendix A

### An Article in the *San Francisco Daily Evening Bulletin*

This is an article about the concept of seismic early warning system in the San Francisco Daily Evening Bulletin (Cooper, 1868).

... we are now obliged to look for some ... means of prognosticating [earthquakes] and I wish to suggest the following mode by which we may make electricity the means, perhaps, of saving thousands of lives in case of the occurrence of more severe shocks than we have yet experienced. It is well known that those shocks are produced by a wave-motion on the surface of the earth, the waves radiating from a center just as they do in water when a stone is thrown in. If this center happens to be far enough from [San Francisco], we may be easily notified of the coming wave in time for all to escape from dangerous buildings before it reaches us...

A very simple mechanical contrivance can be arranged at various points from 10 to 100 miles from San Francisco, by which a wave of the earth high enough to do damage will start an electric current over the wires now radiating from this city and almost instantaneously ring an alarm bell, which should be hung in a high tower near the center of the city. This bell should be very large, of peculiar sound, and known to everybody as the *earthquake bell*. Of course, nothing but the distant undulation of the surface of the earth should ring it. This machinery would be self-

acting, and not dependent on the telegraph operators, who might not always retain presence of mind enough to telegraph at the moment or might sound the alarm too often.

Of course, there might be shocks the central force of which is too near this city to be thus protected but that is not likely to occur [often].

## Appendix B

# Peak Ground Motion Database

This chapter shows the dataset of the peak value of strong motion records used in chapters 3 and 5. The summary of the dataset is shown in table B.1. It consists of strong motion records of ten earthquake with magnitude greater than 6.0. Table B.2 is a list of the peak values of the strong motion records. The jerk, acceleration, velocity and displacement of EW, NS, srss horizontal, UD components are shown in the table.

Table B.1: Earthquake data set used for the near-source (NS) and far-source (FS) ground motion analysis. The left column is the earthquake ID number corresponding to the next table. Moment magnitude ( $M_w$ ) is cited from Harvard CMT solution. The definition of the near-source station is a station with fault distance less than 10 km. The fault models are used as selection criteria to classify near-source stations.

No.	Earthquake	$M_w$	NS	FS	Total	Fault Model
1	Imperial Valley (1979)	6.5	14	20	34	Hartzell and Heaton (1983)
2	Loma Prieta (1989)	6.9	8	39	47	Wald et al. (1991)
3	Landers (1992)	7.3	1	112	113	Wald and Heaton (1994)
4	Northridge (1994)	6.6	17	138	155	Wald et al. (1996)
5	Hyogoken-Nanbu (1995)	6.9	4	14	18	Wald (1996)
6	Izmit (1999)	7.6	4	13	17	Sekiguchi and Iwata (2002)
7	Chi-Chi (1999)	7.6	42	172	214	Ji et al. (2003)
8	Denali (2002)	7.8	1	29	30	Tsuboi et al. (2003)
9	Parkfield (2004)	6.0	47	28	75	Ji et al. (2004)
10	Niigataken-Chuetsu (2004)	6.6	9	58	67	Honda et al. (2005)
Total			147	623	770	

Table B.2: Peak values of the strong motion records for ten earthquakes. The first column is the earthquake ID number corresponding to the table B.1, and the sequential number of the records. Station ID, Longitude and latitude of the station are shown the next column. NF is a binary near-source and far-source classification. NF is 1 if the station is near-source record, and 0 if far-source.
